#### Glenn Alvah Piper III

Submitted to the Department of Ocean Engineering on May 16, 1985 in partial fulfillment of the requirements for the Degrees of Master of Science in Mechanical Engineering and Master of Science in Naval Architecture and Marine Engineering. The author hereby grants to the U.S. Government permission to reproduce and to distribute copies of this thesis document in whole or in part.

#### **ABSTRACT**

An experimental apparatus to measure the particle density distribution in the freeboard of an atmospheric fluidized bed was designed and constructed. The density versus height measured by the sampling apparatus gives a similar exponential decrease as previous investigations have found.

A particle trajectory model is developed which calculates the height and particle density distributions above the bed surface of an atmospheric fluidized bed. The parameters input to the model are the superficial velocity, initial particle velocity, gas jet velocity and duration, and the particle size distribution of the bed mass. The model was evaluated using the experimental data for jet velocity, duration, and particle size. The predicted slope of the particle density versus height in the freeboard agrees with the experimentally measured slope within 20%.

A sensitvity analysis, using the trajectory model, resulted in a determination of the particle distributions in the freeboard of a fluidized bed as affected by varying the input parameters to the trajectory model. The most significant effects were achieved when the jet velocity or duration was altered. ( $\mathcal{T}/_{LC-CS}$ )

Thesis Supervisor: Dr. Leon Glicksman

Title: Senior Research Scientist

The authors hereby grants to M.I.T. and to the U.S. Government permission to reproduce and to distribute copies of this thesis document in whole or in part.

#### **ACKNOULEDGEMENTS**

This thesis was prepared under the guidence and supervision of Dr. Leon Glicksman. His encouragement, patience, advice and understanding were all greatly appreciated, for without them, this work would not have been possible.

The help and support of Tom Yule, who freely gave his time, expert advice and assistance, is most strongly appreciated. I sincerely thank him for his efforts.

A special word of appreciation is given to the Tennessee Valley Authority for funding this research and making it all possible.

Most of all, I would like to thank my fiancee Heide, for her support, understanding, assistance and love during the entire project. She was always there when I needed her, even when her own work was laborsome.

#### CHAPTER I

#### INTRODUCTION

Fluidized beds have been used in industry for many years. They have been used to mix and dry particulate materials and are the principle process in catalytic cracking plants. In the past decade or so, the use of fluidized bed combustors for power generation has become a source of major interest. Prototype coal burning beds have already been built which are comparable to existing coal plants. Fluidized bed combustors have the added benifit of low NOx, SO<sub>2</sub> and hydrocarbon emissions and the flexibility of being able to burn a wide range of fuels ranging from refuse and high sulfur content coal to high grade fuels.

A fluidized bed [Fig 1] is composed of a distributor through which an air flow is introduced through thousands of small orfices. This air then passes through the dense zone of the bed which is comprised of a mass of particles. The air velocity through the dense zone is maintained above the minimum fluidization velocity (Umf) during normal operations. At velocities equal to or greater than Umf, the frictional force (Drag) of the air flowing past a particle is equal to the weight of the particle. Under these conditions, the particle mass behaves very much like a fluid. It will maintain a horizontal surface if the container is tilted, flow out of holes in the

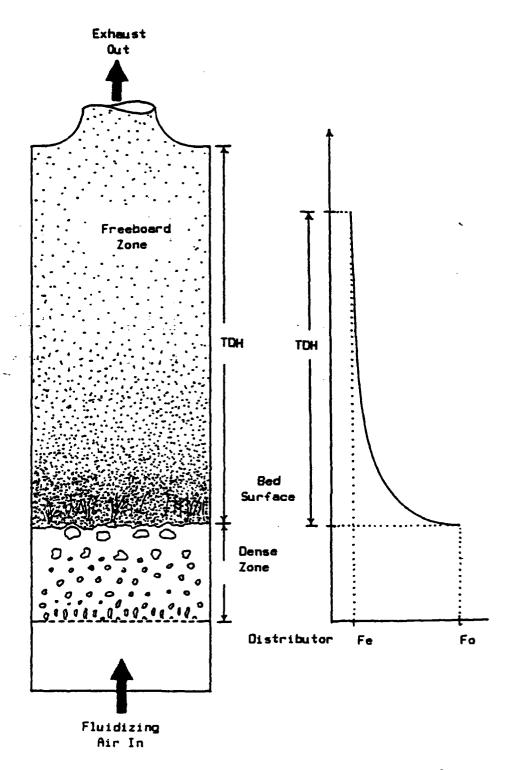

Fig. 1 Model of a fluidized bed. Particle entrainment decreases exponentially with increasing freeboard height.

container, and has a pressure drop across any section of the bed approximately equal to the weight of air and particles in the section [1]. At velocities above Umf, the excess air will coalesce and form small voids or bubbles as it procedes towards the surface of the fluidized bed.

As bubbles break at the surface of the bed, the solid particles are thrown up above the bed surface and are entrained by the upward flowing gas stream. This zone above the bed surface is the freeboard zone. In the freeboard, some particles are carried by the gas flow far above the bed surface and are removed from the fluidized bed (elutriated), while the remainder fall back to the bed. In general the amount of bed solids suspended in the freeboard (entrainment) decreases exponentially along the freeboard height. This distribution is similar to that of the Maxwell-Boltzmann distribution for the case of discrete energy states as it applies to the Law of Atmospheres [2].

$$N(z) = No \exp\{-mgz/kT\}$$
 (1)

Research in the area of entrainment by Lewis et al. [3], Zenz and Weil [4] and others has resulted in the following correlation for entrainment as a function of gas velocity and freeboard height for small-particle beds [1].

$$\frac{F}{At Uo} = B \exp(-(b/Uo)^2 + a H 1)$$
(2)

uhere:

F = Entrainment

At = Area of bed

Uo = Superficial velocity through bed

B = Particle dependent constant

b = Particle dependent constant

a = Particle dependent constant

H = Height of freeboard

At some point above the bed surface, the quantity of
entrained particles becomes constant. At this point, the free
fall velocity of the remaining particles is equal to or less than
the uniform superficial operating velocity. The height at which
the entrainment becomes constant is called the transport
disengagement height (TDH) [1].

The particles that are thrown above the bed are affected in the freeboard region by hydrodynamic parameters such as: bubble size, bubble frequency, fluidizing velocity, height above the bed, particle size, particle density, column diameter [5], and baffles [6]. The intermittent high velocity bursts of gas which occurs when a bubble bursts, imposes a flucuating and highly irregular time dependent velocity profile over the cross section of the bed surface. At successively higher levels above the bed surface, this velocity profile becomes more and more uniform until at the TDH, the flow is at the uniform superficial operating velocity (Uo) [4].

Until recently, little attention was paid to the understanding of the freeboard reactions for large particle beds. However, due to recent work in fluidized bed combustors, the extent of particle and fines loading in the freeboard has been shown to significantly affect the  $SO_2$  absorbtion, NOx reduction, COemission. In general, the last 5 to 10% of the combustibles will burn in the freeboard. It was shown that the fine sorbent particles entrained into the freeboard will enhance sulphur capture and that entrained char particles will react with NOx and reduce its emission [7]. Fines reinjection has been shown to significantly increases the fine particle concentration in the bed and in the freeboard with the consequence of further enhancing char oxidation. However, this can result in overheating in the freeboard region and excess  $SO_7$  and NOx emission [7]. The end result is that the potential for fluidized bed combustion power plants is enhanced by their ability to burn high sulphur content fuels and maintain low  $SO_7$  emissions. Further research in the area directly above the bed surface is required to properly model the reactions occurring within the freeboard.

Extensive studies on entrainment rate and elutriation have been made with numerous correlations, some of which are proposed in [1, 3, 4, 5, 6, 7, 8]. However, most of the reported work on entrainment from fluidized beds has been carried out with either a closely sized fraction of particles or a mixture of two such fractions. Virtually all of this work has been conducted on bench scale or catalytic cracking fluidized beds. The results of these

than full sized beds or tend to operate in the slugging condition. Therefore, the entrainment rates and transport disengagement heights (TDH) for fluidized beds are generally estimated from empirical or semiempirical correlations obtained from this data and most of them show extreme discrepancies between different experimental results. Extrapolation of these empirical correlations usually leads to strange results [5] with discrepancies which can vary by two orders of magnitude.

difficulty in obtaining accurate entrainment rate data. Most of the data is based on pressure measurements at incremental heights in fluidized cracking plant type beds [11]. The effect of wall loading by particles and the actual relation between pressure and particle concentration is considered to be major sources of error when using this method with large particles. As a result, none of the correlations are widely accepted as giving accurate predictions [8].

A complete model of the entrainment process from fluidized beds must take into account all the mechanisms involved within the process. The arrival of bubbles at the bed surface, ejection of particles from the dense-phased bed into the freeboard region as the bubbles erupt, particle-particle interactions, and the trajectories of ejected particles are all important [8]. Much work has been done concerning bubble growth, velocity, volume,

etc. and their behavior is fairly well understood.

The mechanism of solids ejection at the bubbling bed surface is still not well understood. The origin of ejected particles is reported to be primarily due to two sources. The particles which . have been lifted by the bubble wake and thrown upwards following the bubble burst at the surface is the first source. This theory is supported by work done by George and Grace [8] who performed experiments which concluded that the vast majority of the ejected particles did not originate from the surface layers but from bubble wake pick up. Work done by Page and Harrison [6] also appears to agree with this. The second theory suggests that the ejected particles originate at the nose of the bursting bubbles and are thrown outward when the bubble breaks. Research by Rowe and Partridge [8] and Glicksman et al [12] have shown this second mechanisim as being the dominate particle ejection source and thus supporting this second theory. Their work has also shown that under the conditions in which 2 bubbles coalesce just below the surface of the bed, the jet of gas produced can result in a significant amount of particles being ejected from the wake of the first bubble.

The effect of multiparticle interactions have been for the most part ignored except by Peters and Prybylouski [13]. The motion of any individual particle is influenced by the presence of other particles, i.e., through direct particle-particle interactions and deviations in the fluid drag force. The major

drawback of their work is that the paper compares their theory with only a single set of experimental results [3].

Studies to model the trajectories of particles in the freeboard have been conducted several times. The work of Walsh et al [7], George and Grace [8], and Peters and Prybylouski [13] name just a few of the latest efforts. All of these studies relied upon experimental data to develope their theories. However, to check the accuracy of their theories, more experimental data is required.

As of yet, none of the entrainment models available can be incorporated into fluidized bed combustion models with sufficient accuracy to warrent their use. This is due to a lack of experimental information on entrainment rate as a function of the complete fluidization parameters of the bed to test the models with. As a result, the purpose of this study has been to obtain particle density distributions above a cold atmospheric fluidized bed containing a continuous particle size distribution [Appendix E1.

#### CHAPTER II

#### PARTICLE SAMPLING APPARATUS

#### <u>Design Alternatives</u>

distributions in fluid flows. The more commonly used methods are:

- [ ] Catching mechanisms
- 3 ) Trapping mechanisms 2) Trapping mechanisms
  - 3) Radiation attenuation measurements
  - 4) Optical measurements
  - 5) Capacitance and Inductance measurements

Catching mechanisms are passive devices. That is, particles are captured merely by the presence of the catching mechanism in the fluid flow contains the particles to be sampled. The data obtained using this method is position dependent and produces average values for the particle flux loadings. These catching mechanisms are also limited in that they can only catch particles with particle fluxes traveling in a single direction. The device used by Walsh et al [10] only captured falling particles while the device used by George and Grace [8] required the upward moving particles to deflect off of a baffle surface and fall into a collecting trough.

Trapping mechanisims, unlike catching mechanisms, are active particle samplers. Their operation involves the trapping and isolation of a finite volume of the fluid flow at a specific period in time. This sampling technique produces time dependent as well as position dependent data. This will allow correlations between bubble eruption and pacticle density to be made using multiple bubble conditions rather than single bubble capture. As the number of random samples taken by this method increases, the average value of this data will approach that of the catching mechanism. Trapping mechanisms also capture particle fluxes traveling in multiple directions. This ability reduces the error inherent in measuring only the downward or only the upward particle flux. The apparatus used in this paper is a trapping mechanism.

Attenuation of nuclear particles from a radioactve source can be used to give average particle density distributions across a suspension. However, this method is not adaptable to density determinations at a point. An average time dependent density determination can be achieved with this method. Another draw-back of this method is the radiation hazards involved with the use of nuclear particles.

Optical density determinations consists of two separate methods. The first method uses a very small light beam which is eclipsed by the transition of a particle through it. A related

method uses the absorbtion and scattering of a somewhat larger light beam to correlate the change in light intensity with particle density. This method has been used frequently in the study of aerosols but requires complicated and intricate equipment [141. The second method involves high speed photographs of a small volume of space. This method cannot be used when the particle density is so large that multiple particles eclipse each other frequently enough to produce unacceptable error. This is the case when the probe height above the bed is less than 7-15 cm (3-6 in).

a toroidial inductor or a parallel plate capacitor in the flow.

The presence of the particles changes the permeability and thus the inductance of the inductor, or the dielectric strength and thus the capacitance of the capacitor. The draw-backs of these methods involves the unknown effects of particle velocity and external particles on the inductor and charge transfer to particles from the capacitor [14].

#### Apparatus Requirements

The goal of this study was to determine the density distribution of particles above an atmospheric fluidized bed with particle velocities of up to 10 meters per second. The particle size distribution of material ejected from bubbles is required for particle trajectory calculations. A correlation between the

average density and the density present immediately after a bubble bursts from the bed surface was also of interest. These requirements dictated that the method used for measuring densities have the following capabilities:

- 1) Measure densities with good spatial resolution.
- 2) Measure densities at specific moments in time.
- Detain particle size information.
  - 4) Operate under extremely dirty conditions.
  - 5) Easy sample removal from bed.
  - . 6) Remote operation of sampler.

The radiation attenuation and inductance/capacitance methods can not determine particle sizes. Therefore, these methods were no longer considered as possible measurement alternatives.

Because the optical methods are either not reliable at small heights above the bed or their use is too complex, they were not used. Catching devices, although simple to use, do not have the ability to measure data at specific points in time and determine particle density loading in space. As a result, the determination to use a trapping mechanism as the method of measuring particle densities was made.

#### Apparatus Design

#### General Design Criteria

The following criteria was used in determining the design of the trapping device.

- - The apparatus must be capable of frequent sampling without requiring access to the sampling device itself.
  - The samples trapped, must be easily accessable from outside the fluidized bed without interupting the bed conditions.
  - 4) The apparatus must be able to operate in the high particle flux environment of the fluidized bed.

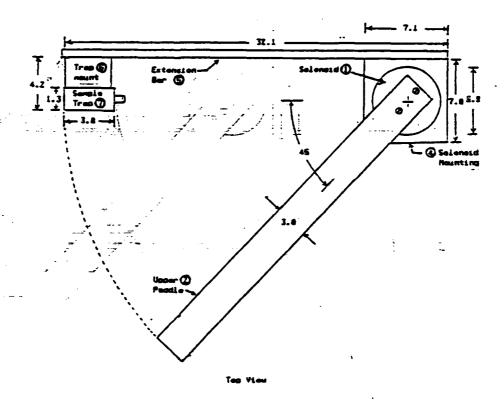

5) The actuation of the trapping device must be able to be accurately determined to allow correlation with other time resolved measurements.

#### General Design

The apparatus is shown in Figs. 2 and 3. A description and list of all components is given in Appendix H. The sample container is mounted on an extension arm to minimize the disturbance to the air flow around the sample trap caused by the rest of the mechanism. The sample container is closed using two (2) paddle arms, one above and the other below. These paddle arms are attached to aluminum interfaces which are used to connect them to a rotary solenoid. The solenoid is used to swing the paddles over the sample trap and shut it. Not shown in these figures are the power supply for the solenoid, the vacuum system used to remove the particles from the sample trap and the water-proof nylon shell used to keep the particles from interfering with the operation of the solenoid. All of these systems are described in greater detail in the following sections.

#### Sample Container

To ensure that the sampling device had minimal effect on the fluid flow, the cross sectional area presented to the flow had to be minimized. This constraint required that the sample container

be separated from the rest of the apparatus. This was benificial in the final design because it helped to reduce the apparatus closure time.

To ensure a good seal was achieved when the trap was shut, felt was used as a gasket between the sample container and the was maddless? Fig. 4 shows the final design used for the sampling mechanism. It is constructed of 1/16 inch aluminum with 1/4 inch square stock used for the frame and mounting structure.

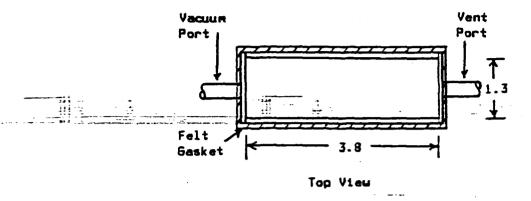

Epoxy is used to seal the sides of the container.

#### Closure Paddles

After several iterations on paddle designs, it was determined that the paddle construction which offered the greatest stiffness for the least weight was a composite laminate. The paddle, shown in Fig. 5, is made using a 0.4 in thick foam core with 1/32 inch thick Basswood laminations on the exterior. Hardwood (Maple) end pieces were used to provide a noncompressive connection between the foam paddles and the aluminum interfaces. The aluminum interfaces couple the solenoid shaft to the paddles. Epoxy was used to join the laminate materials.

#### Actuator

A rotating mechanism utilizing a rotary solenoid was chosen to shut the sample trap. A rotary solenoid was selected because

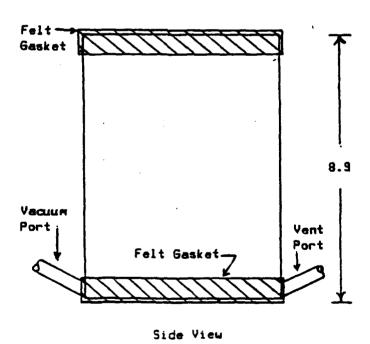

Fig. 4 Top and side view of sample trap.
Dimensions in cm.

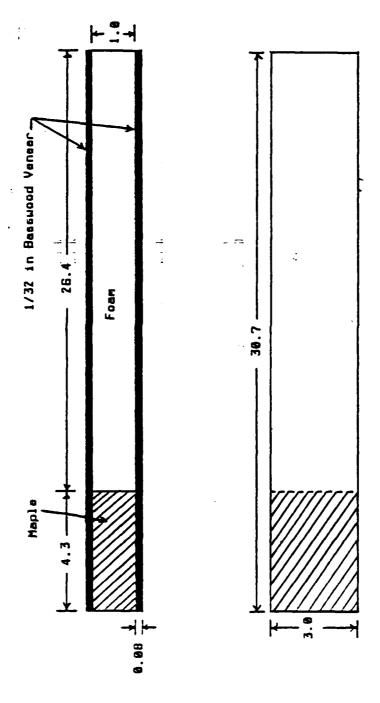

Fig. 5 Design of Closure Paddles. Dimensions in cm.

of the problems of maintaining low friction surfaces for sliding mechanisms in the presence of the particulate matter being sampled. This precluded the use of any sliding mechanism to shut the sample trap. The calculations found in Appendix A and Appendix C determined the size of the solenoid required to achieve the desired closure time.

The 45 degree stroke solenoid was chosen to place the paddle arms far enough away from the sample trap, such that when de-energized it prevents interference with the particle flow. This stroke also minimized the area which must be clear of obstructions to the travel of the paddles. The solenoid operates at a 1/10 duty cycle power rating when initially actuated, providing the torque output shown in Fig. 6. After the solenoid has shut the sample trap, the solenoid is operated at a lower power rating, providing a holding torque of 5.5 in-lbs. This decreased rating is necessary to prevent overheating of the solenoid. This assembly is encased within a nylon shell.

#### Power Supply

Fig. 7 is a schematic of the electrical system used to power the solenoid. Appendix H contains a list of all components used in the power supply. The power supply plugs directly into a standard 115 volt AC line source. Switch S1 is used to apply power to the solenoid M1. The full wave bridge rectifier assembly converts the AC line voltage to DC. The rectifier assembly is

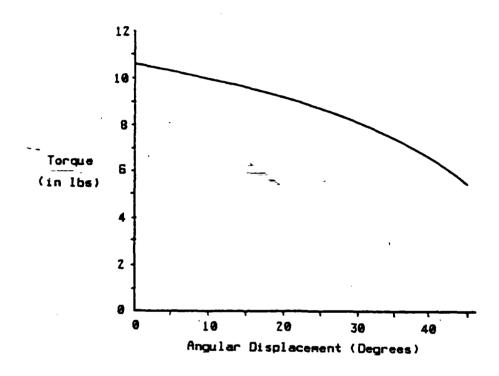

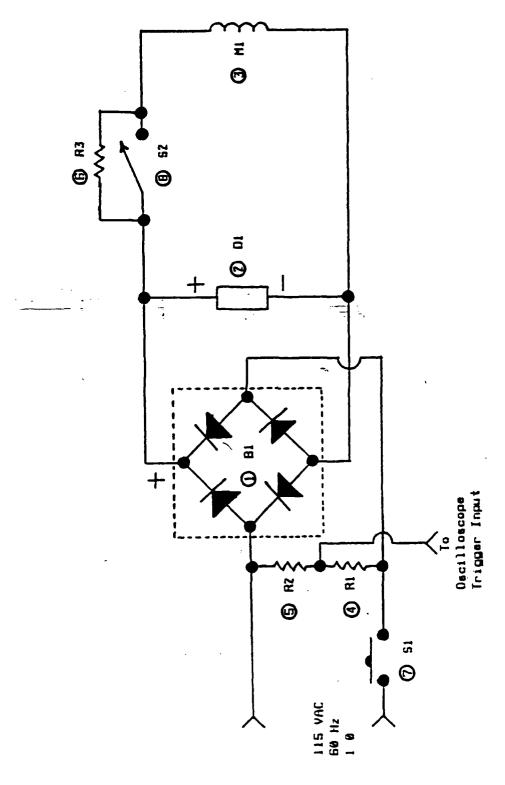

Fig. 6 Torque Output Curve for Rotary Solenoid.

word expressions appropriate

Fig. 7 Schematic of Solenoid Power Supply.

O Reference number for component list in Appendix H.

protected by the arc suppresser O1 from the large voltage spike induced in the solenoid coil when the solenoid is actuated.

Resistor R3 is used to reduce the current through the solenoid after the solenoid has been closed to prevent it from overheating. To initially shut the sample trap, full current is applied to the solenoid by shutting switch S2, which bypasses resistor R3.

Resistors R1 and R2 form a voltage divider network to provide a low voltage (5.5 volts AC) trigger source for an oscilloscope.

### Vacuum System

To remove the particles in the sample trap, a vacuum system was developed. This system is shown in Fig. 8 with a list of the components given in Appendix H. A vacuum is produced by allowing air from a 100 psi air source to flow through valve V1 into the venturi eductor P1. The vacuum places a suction on the sample container CZ via a fine mesh screen. The purpose of this screen is to prevent particles from escaping the sample container. The suction is applied to the sample trap C1 through 1/4 inch polyflow tubing. It is through this tube that the particles are removed from the sample trap and collected in the sample container. An equalization and agitaion line is connected to the opposite side of the sample trap. This line serves two purposes. First, it ensures that the vacuum system does not pull in particles from outside of the sample trap. Second, it allows a flow of air to be introduced which stirs up the particles trapped inside. This helps push them into the suction line and reduce the remaining particles to a minimum.

### Apparatus Testino

Two tests were run to determine the effectiveness of the system. The first test determined the closing time of the sample trap. The second evaluated the error from the loss of particles which were left in the sample trap by the vacuum system.

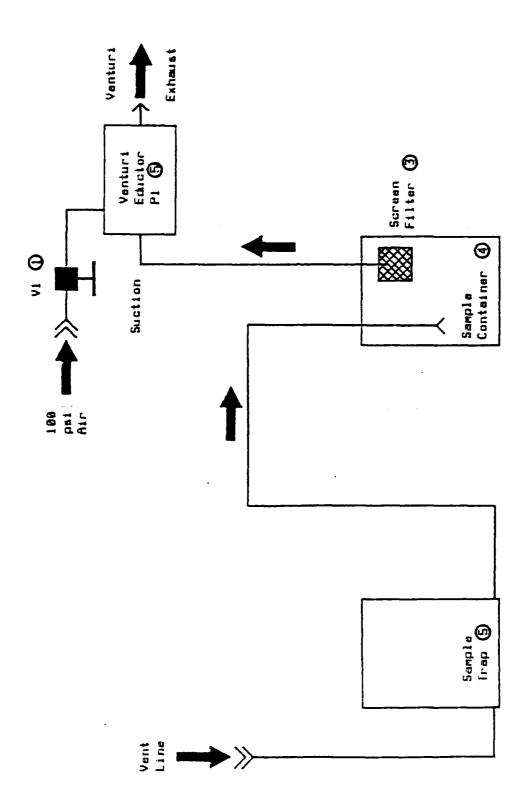

Fig. 8 Schematic Diagram For Vacuum System.

O Reference number for component list in Appendix H.

The procedure and method used to determine closure time for the sample trap is given in Appendix C. From the results of these tests given in Appendix C, the closure time was determined to have an average value of 1.44 milliseconds. This is equal to a 10 m/s particle traveling 1.44 cm or approximately 16 % of the sample trap length. The average particle velocity will be less than 2 m/s and will therefore introduce an average error of less than 3 %.

Using the sample trap closure time, a dynamic analysis determined that the total time from initially applying power to the solenoid until it shut the sample trap is 42.6 milliseconds.

These calculations are given in Appendix D. This actuation time is important for determining whether a specific bubble's debris was within the vicinity of the trap at the time of closure.

The procedure and results for the testing of the sample removal vacuum system are given in Appendix B. The average amount of particles just by the vacuum system was determined to be 0.52 % of the initial sample placed in the trap. The maximum error was 0.93 %. The error from the vacuum system is therefore considered to have an insignificant effect on the data obtained.

#### CHAPTER III

### EXPERIMENTAL PROCEDURE

### Fluidized Bed Configuration

The M.I.T. atmospheric fluidized bed, in which the sampling device was used, is a model of the 20 MW atmospheric fluidized bed combustor prototype, jointly sponsored by the Tennessee Valley Authority and the Electric Power Research Institute. The fluidized bed model is described in Lord et al [15] and Jones et al [16]. While using the sampling apparatus, a different heat exchanger tube bundle configuration was used than is described in ones et al [16]. The heat exchanger configuration used is shown in Figs. 9 and 10.

The heat exchanger used during this work is made of 1.25 cm (0.5 in) 0.D. tubing arranged in 4 rows of 22 pipes each. The tubes are aligned as shown in Fig. 10. Each pipe is spaced with a vertical center to center distance of 5.08 cm (2 in) and a horizontal center to center distance of 3.91 cm (1.5 in). The distance from the distributor to the center of the upper most tube is 27.62 cm (10.875 in). A 5.08 cm (2 in) spacing separates the front and back walls of the fluidized bed from the end tubes of the bundel. The cross sectional area of the bed is 1.079 sq m (11.61 Sq Ft). The particulate material used in the bed is a

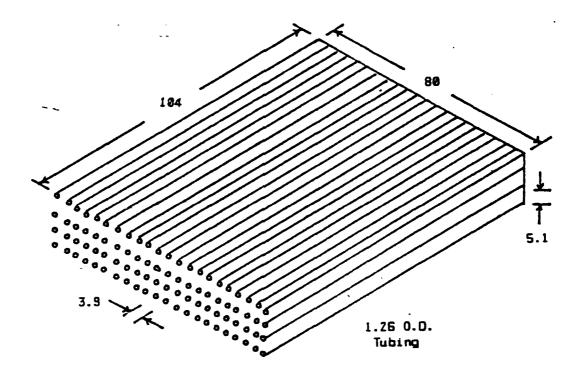

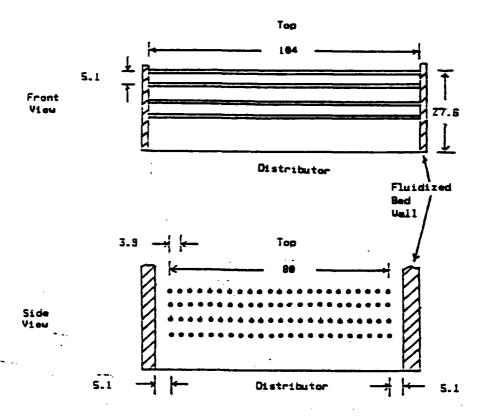

Fig. 9 Heat Exchanger Tube Design Showing The Four (4) Rows of 22 Tubes.
All Dimensions in cm.

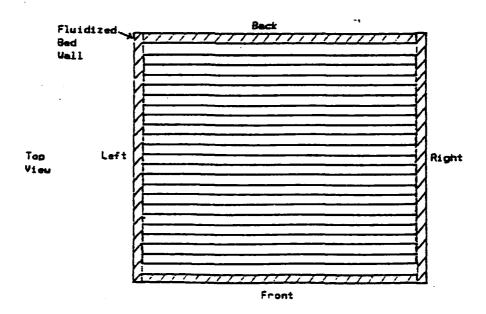

Fig. 10 Heat Exchanger Tube Design. All Dimensions in cm.

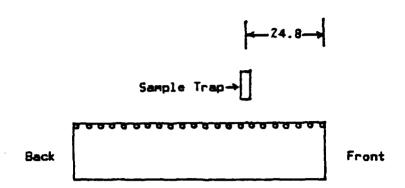

mixture of steel grit abrasive having a specific gravity of 8.1.

Appendix E lists the size distribution of the steel grit used during the sampling operation. The bed was operated without recycling the fines captured in the cyclones. The static bed height of the material was 22.54 cm (8.875 in) throughout the data collection period.

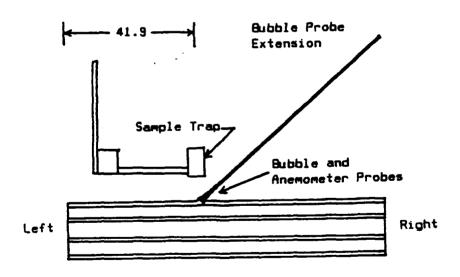

# Equipment Set-up

Fig. 11 shows the placement of the sampling device inside the fluidized bed. The sample trap was positioned such that it was directly over a spacing between tubes [22.86 cm (9 in) from the center of the front-most tubel and 41.91 cm (16.5 in) from the left wall. The height of the sample trap above the distributor was varied during the sampling process as discussed in the section on sampling procedure.

Fig. 12 shows the placement of the bubble probe and the anemometer probe with respect to the sample trap. The bubble probe was placed directly below the sample trap and 26.67 cm (10.5 in) above the distributor. The probe extension was placed at an angle so as not to interfere with the sample trap operation. To protect the anemometer wire from particles impacting it, a special shield consisting of # 320 mesh screen and an aluminum frame was placed around it. The anemometer probe was attached to the bubble probe extension with the entrance to the anemometer probe 29.21 cm (11.5 in) above the distributor. This placed the entrance to the

anemometer probe 2.54 cm (1.0 in) away from the center of the sample trap and 0.64 cm (0.25 in) outside the area directly below the sample trap. As a result, the probe has a minimum effect on the air flow from the bed to the sample trap, but will only measure the gas velocity at the edge of the sample trap perimeter. The positioning of the two probes above the distributor remained constant throughout the sampling evolution.

Fig. 13 is a block diagram showing the equipment used during the sampling operations and their interconnections. Table 1 is a listing of the equipment used. The oscilloscope time base was set for MANUAL TRIGGER, SINGLE SWEEP mode and a sweep time of 50 ms/div. The channels of the dual trace amplifier were set at 5 volts per division for the bubble probe and 2 volts per division for the sample trap inputs. On the differential amplifier, one channel was not used and the second channel was set at 1 volt per division for the anemometer probe input.

Listing of equipment used during particle sampling operations.

To determine the fluidization conditions within the bed, a set of manometers were used. These manometers measured pressures within the bed, at heights from 4.13 cm (1.62 in) to 37.15 cm (14.62 in) above the distributor, in 2.54 cm (1 in) increments. The pressure data corresponding to each trap position and bed velocity is listed in Appendix I.

To determine the gas flow conditions within the bed, an orfice flow meter with 1D - 1/2D taps was located upstream of the distributor. The computer program listed in Appendix G was used to convert the pressure tap data to mean air velocities within the bed.

### Sampling Procedure

Data was collected for four (4) mean bed velocities at six

(6) different sample heights. The sample trap was placed at a given sampling height (measured from the distributor to the bottom of the trap), and ten (10) samples were collected at each desired velocity. The trap position was then changed to a new height.

During certain sampling conditions, those which involved low sampling heights with the higher air velocities, the paddle arms would occasionally impact the sides of the sample trap and not close the sample trap completely. It is assumed that this occurred

when a large bubble erupted directly under the paddle arm and deflected the paddle arm into the side of the trap. Whenever this occured, the trap was de-energized and the closure cycle repeated.

Each time the height or velocity was changed, a complete sampling cycle was conducted and this sample discarded. This was to prevent any accumulation of particles (in the entrance to the vacuum or purge lines on the sample trap) from being added to the first sample at the new height or velocity.

For each set of data at a given height and velocity the following information was recorded:

- 1) Fluidized bed height above the distributor determined visually and by pressure measurements.
- 2) Pressure upstream of orfice plate (P1)
- 3) Pressure difference across orfice plate (delta P)
- 4) Air temperature in bed
- 5) Pressure distribution in bed
- 6) Height of sample trap above distributor

The following procedure was used during sampling:

# B. Sampling Procedure

- 1) Trigger oscilloscope sweep and wait until sweep is at the center of the CRT.
- 2) Close the Solenoid power supply switch S1. When S1 is shut, the oscilloscope will show an additional trace. This third trace is used to determine the closure time relative to the presence of gas jets and bubble eruptions. An example of a typical oscilloscope trace is shown in Fig. 14.
- 3) Open the solenoid trigger switch S2. This reduces the current to the solenoid to prevent overheating. The maximum allowed time to let S2 remain closed is five (5) seconds.
- 4) Turn on the air supply to the vacuum system and leave on one (1) minute. The exhaust air from the venturi on the vacuum system must be directed into the purge line in an oscillatory manner.

  This will agitate the particles within the trap

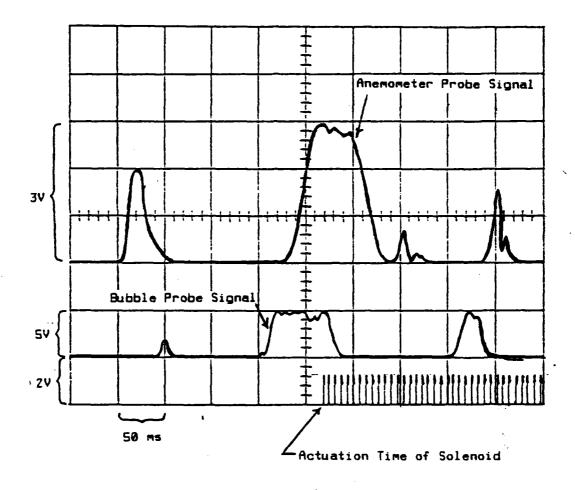

Fig. 14 Typical Oscilloscope Trace Obtained Ouring Sampling Operation.

so as to move them into the vacuum line.

- 5) Turn off the vacuum air supply.
- 6) Turn off the solenoid power supply switch S1.
- 7) Remove sample from sample container and place in specimen bottle.
- 8) Photograph trace on oscilloscope.
- 9) Repeat from A.

### Sample Analysis

Sample Weight Determination

Each sample obtained was weighed, using a Torsion Balance Co.

TORBAL scale, to an accuracy of 0.01 grams. The average value and standard deviation was then determined for each set (specific height and velocity) of samples. The weight of particles in a completely filled sample trap was also determined for void determination. These results are listed in Appendix I.

### Determination of Particle Size Distribution

To determine the particle size distribution which occurs at various heights for a specified gas velocity, three (3) samples from each set of data at a specified height and velocity, and from the bulk bed material were analyzed using a Zeiss Videoplan Z Image analyzer. The software used was the "Image Analysis System MOP-Videoplan" distributed by KONYRON Electronics Group.

For each sample selected, a microscope slide was prepared using double sided adhesive tape on which a portion of the selected sample was placed. To ensure a sharp contrast was achieved, each slide was backed with white paper. The sample was then placed under a Zeiss microscope to which the image analyzer was connected via a vidiocon tube. The magnification used was 50X which provided an average view of about 8 particles at a time. The analyzer was then used to analyze the partices present on each slide of interest. The mode in which the image analyzer was used was the equivalent diameter mode. This mode determined the cross sectional area of each particle sampled and calculated the diameter of a circle with the same area. When a data set was completed, the data was analyzed for particle size distribution. The resulting output (Appendix J) consists of a particle count vs particle size histogram, a cumulative frequency plot and a classification data list. A gaussian distribution fit for the data is also plotted on the histogram and cumulative frequency

plots. The X axis of the plots are normalized with a range of zero (0) to four (4). To determine the actual diameter of the particle in microns for a given normalized value, the normalized value must be multiplied by the conversion factor 248.887.

### CHAPTER IV

### COMPUTER MODEL

#### Introduction

1

This chapter descibes the theory, logic flow and testing of a particle trajectory computer model to predict the particle loading in the freeboard due to erupting buubles. The program, listed in Appendix L, is written in HP BASIC 2.0 and was run on a Hewlett Packard 9816 microcomputer. The output from the model is discussed in chapter VI and compared with experimental results. An in depth analysis of the program logic and structure is given in Appendix L.

# Model Theory

The model developed here, is based on calculating the trajectory of a single particle as it is ejected from the bed surface and is acted upon by gravitational and drag forces. The drag force is due to the difference in absolute particle and air velocities. The air velocity is a combination of the initial jet velocity produced when a bubble bursts, and the superficial bed velocity. To ensure that the particle drag is calculated accurately, the following drag coefficient correlation given by White [17] was used.

$$Cd = \frac{74}{Re} + \frac{6}{1 + \sqrt{Re}} + 0.4$$
 (3)

where:

Cd = Drag coefficient for sphere Re = Reynolds number

Eqn 3 is valid over the range  $0(\text{Re}(10^5))$ . To calculate the particles position and velocity, the computer uses a forward difference method. Using Newton's Law ( $\Sigma F=ma$ ) the acceleration of the particle due to gravity and drag is determined. Inserting this acceleration into Eqn 4, the particles new velocity is determined.

$$V = Vo + a t$$
 (4)

uhere:

V = Particles new velocity
Vo = Particles present velocity
a = Acceleration of particle
t = Time increment of calculation

To determine the particles new position, the velocity calculated in Eqn 4 is inserted into Eqn 5.

$$H = Ho + \frac{(Vo + V) + v}{2}$$
 (5)

where:

H = Particles new height

Ho = Particles present height

Vo = Particles present velocity

V = Particles new velocity

t = Time increment of calculation

Using Eqns 3,4, and 5, the trajectory of the particle is calculated from the time it initially leaves the bed until the time that it returns to the bed.

These calculations are repeated over a range of particle diameters from 80 to 570 microns. By determining the residence time of each particle within a specified height increment ( $\Delta$  H) above the surface of the bed, a particle density distribution above the bed is determined. The height increment ( $\Delta$  H) used in the program is 2 cm. At the end of each time step when the height calculation (Eqn 5) is completed, the counter representing the particular 2 cm height increment which the particle is in, is incremented by one. Each particle size has its own set of counters to allow individual particle analysis.

The calculated density distribution is then weighted with the particle size distribution of the bulk bed material since the

probability of a given size particle being present at a specified height is dependent upon the number of particles within the system. This is accomplished by multiplying each height counter of a given particle size with the number of particles for that given size present in the input bed distribution. By summing the density values for each set of particle diameters at a given height over the entire freeboard of the bed, the overall particle density above the bed surface is determined.

The model assumes that all the particles are ejected perpendicular to the surface of the bed and are initially at a uniform velocity. Because the model uses single particles for the analysis, the effects of multiparticle interactions are not included in the model.

#### Testing of Program

To evaluate the validity of the program, two tests were conducted. The first test compared the height solution produced by the computer with a closed form solution. The second test involved running the program with different particle diameter and particle distribution height intervals to ensure that a valid sample size was being used.

# Closed Form Solution

To determine a closed form solution for particle height as a

function of initial particle velocity and superficial velocity Uo, a force balance was used. The forces acting on a particle are gravitational and drag. The gravitational force, F1, is simply the volume of the particle multiplied by the particles density and the gravitational acceleration, and can be written as:

where:

F1 = Force due to gravity
Pp = Density of particle
D = Diameter of particle
g = gravitational acceleration

In order to get a closed form solution that did not involve non-linear differential equations, Stokes flow was used for the closed form solution only. The computer model used the Stokes equation only to compare results with the closed form solution, afterward, Eqn 3 was used. Using the Stokes drag coefficient relation, the drag force on a particle can be determined as:

$$F2 = 3 (Uo - Up) D$$
 (7)

where:

F2 = Force due to drag
Uo = Superficial bed velocity
Up = Velocity of particle

= Absolute viscosity of air
D = Diameter of particle

By inserting Eqns 6 and 7 into Newton's Law ( $\Sigma$  F=ma) and simplifying, the following differential equation is obtained:

$$\ddot{X} + C1 \ \dot{X} = C2 \tag{8}$$

where:

 $\ddot{X}$  = Acceleration of particle

 $\dot{X}$  = Velocity of particle

 $C1 = \frac{18 \, \mu}{\text{Pp } 0^2}$ 

C2 = C1 Uo - g

boundary conditions:

1) t=0 X=Uo

2) t=0 X=0

This second order linear differential equation can be solved using the given boundary conditions with the resulting closed form solution given as:

$$X = C3 + C2 + C3 \exp(-C1 + C3)$$
(9)

where:

$$X = \text{Height of particle}$$

$$C3 = \begin{bmatrix} U_0 - \frac{C2}{C1} & \frac{1}{C1} \end{bmatrix}$$

Using the initial conditions listed in table 2, the solution obtained using the computer model (maximum height= 15.270 cm, time to maximum height= 0.275 sec) was identical to three decimal places with the solution obtained using Eqn 9.

### TABLE 2

Superficial Velocity (Uo): 60.96 cm/s (2 ft/s)

Particle density: 5000 kg/m³
Time increment (computer): 0.001 sec
Jet velocity: 0.0 cm/s

List of parameters used to check computer calculations against closed form solution.

### Sample Size Sensitivity Test

To ensure that appropriate sample sizes were used to minimize errors due to coarse sampling intervals, two sensitivity tests were run. One test involved changing the particle diameter interval from 10 microns to 5 microns. The second test changed the height sampling interval ( $\Delta$  H) from 2 cm to 5cm and then 1 cm. For each of the tests, the same initial conditions were input into the program. Table 3 shows the resulting output from the program listing the initial conditions and the resulting diameter versus maximum height data calculated. Fig. 15 shows a plot of the calculated maximum height vs particle diameter data listed in table 2.— Fig. 16 shows the bed particle distribution used for each of the tests.

Fig. 17a shows the entrainment calculation using a diameter interval of 10 microns and a  $\Delta$  H of 2 cm. Fig. 17b shows the same calculation using a diameter interval of 10 microns and a  $\Delta$  H of 5 cm. The curve is not as smooth but still retains the same general shape. The peak of the curve shown in Fig. 17b occurs at a height of about 20 cm whereas the peak in Fig. 17a occurs at about 15 cm. A semi-log plot of these curves would show that the slope of the line to the right of the peak would be larger for the data represented by Fig. 17b. The effect of maintaining  $\Delta$  H at 5 cm but decreasing the diameter interval to 5 microns is shown in Fig. 17c. There is no readily detectable difference between Fig.

17c and Fig. 17b. In Fig. 17d, the effect of changing  $\Delta$ H to 1 cm and diameter spacing to 5 microns is shown. The difference between Fig. 17a and Fig. 17d is barely noticable and no detectable change in the slope to the right of the peaks is present. As a result of this analysis, the program was operated with a  $\Delta$ H of 2 cm and a diameter interval of 10 microns. This reduced the calculation time to half of that required when using a diameter spacing of 5 microns when the same total diameter span was used and, as was seen in Figs. 17a and 17d, the difference in output does not require the finer increment.

#### CHAPTER Y

# EXPERIMENTAL RESULTS AND DISCUSSION

# Minimum Fluidization Velocity

through the bed (Pb). The velocity values were determined using the program in Appendix 6 and the pressure data listed in Appendix I. From this plot, the minimum fluidization velocity (Umf) for the bed conditions used during this study is determined to be 0.15 m/s (0.5 Ft/sec).

# Entrainment Analysis

Table 4 lists the averaged sample weights and their standard deviations for the samples (Appendix I) collected by the sampling apparatus. Looking at the standard deviation of the sample groups, the standard deviation is fairly large compared to the average values. However, visual observations of the fluidized bed in operation would suggest that a larger standard deviation would be expected. The short sample cycle (2 ms) and the bubble burst activity in the bed are the main reasons for this conclusion. The average standard deviation is 29 % of the average sample weight

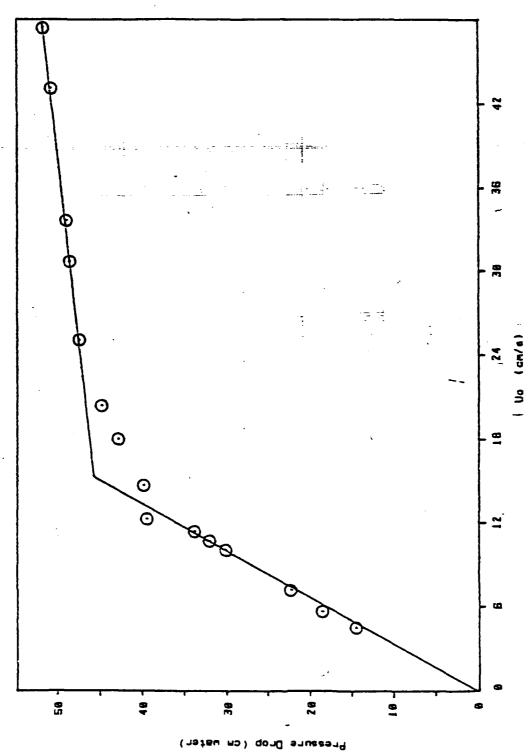

Fig. 18 Plot of Pressure Grop Across Bad vs Uo. The Estimate of Uni from this Plot is 15.2 cm/s (0.5 ft/s).

and the range extends from 68 % of the average for the sample set numbers 106 thru 115 to only 7 % of the average for the samples 285 thru 295. This variation is believed to be due to the nature of the bubble activity within the bed. It would appear that when a bubble erupts at a time just prior to closure of the trap, a sample weight greater than the average would be obtained. However, when no bubble has been present, the material caught by the trap should commist mainly of particles returning to the bed and therefore be below the average weight caught. Table 4 also shows the density of each sample collected. These values were determined by dividing the averaged sample weights by the volume of the sample trap which is 43.02 cubic cm.

115

List of experimental data showing sample averages, standard deviations, heights, and velocity conditions measured. Density values are calculated by dividing the average sample weight by the sample trap volume.

Fig. 19 shows the relationship between the average particle density caught in the sample trap and the sample trap height above the bed surface as a function of Uo/Umf.

For the relatively low fluidization velocities used during the data measurements, (maximum Uo/Umf = 3.81) the freeboard height can be assumed infinite. Using this assumption implies that all of the particles return to the bed and none are elutriated, ie complete reflux. Under these conditions, the following equation has been suggested by Lewis et al [31] and Kunni and Levenspiel [1] to model the particle loading within the freeboard.

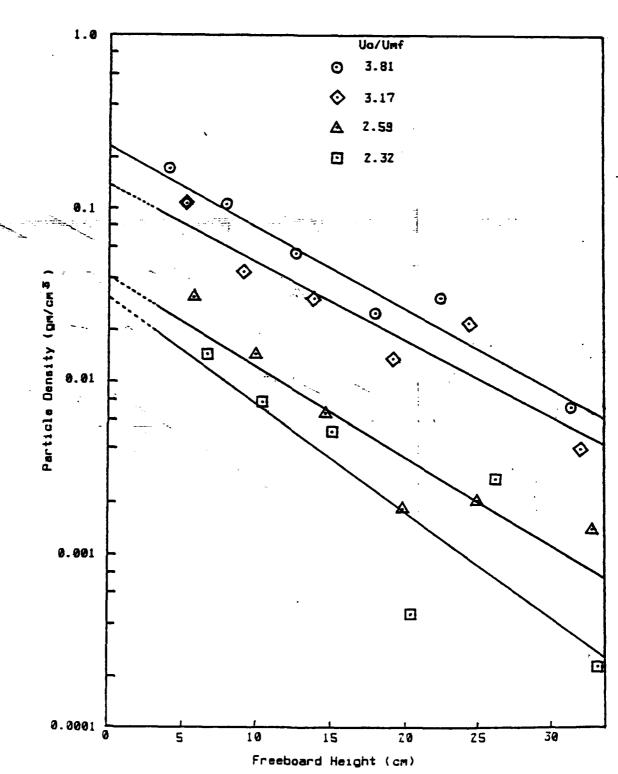

Fig. 19 Plot of Particle Density vs Freeboard Height as a Function of Uo/Umf. This data was Obtained Using the Particle Sampler.

Pr = Po exp{-a 1}

Results of linear regression analysis for particle loading density (grams/cm ) vs height above the bed surface (cm).

The parameter Po physically represents the particle loading density which would be obtained if the sample were taken at the surface of the bed. This is not necessarily the case as is indicated by the computer model which is discussed in chapter VI, but is only a parameter describing the particle loading distribution in the region of the data obtained. The dashed lines below freeboard heights of 4 cm indicate the region in question. The parameter a is a characteristic length of decay for the particle flux.

A correlation between the values for Po in table 5 and Uo/Umf is shown in Fig. 20. This plot shows that Po is closely related with Uo/Umf. Po varies with (Uo/Umf - 1) approximately to the 2.9

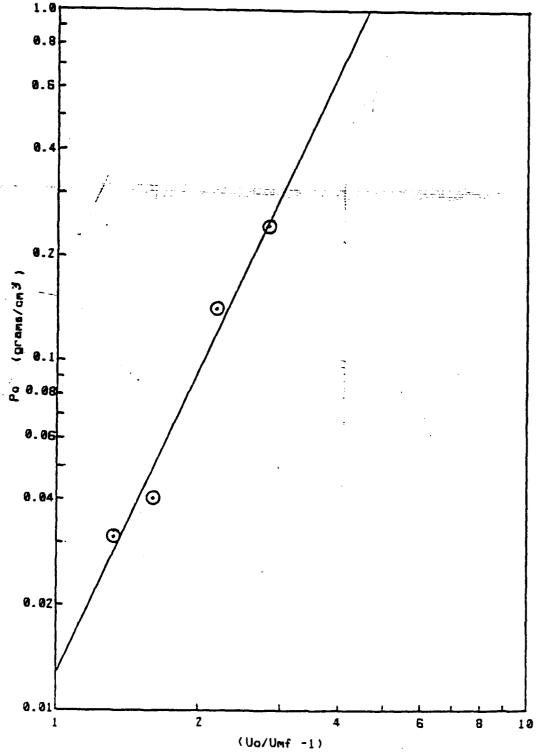

Fig. 20 Plot of Po vs (Uo/Umf -1) Showing Strong Dependence of Po on Uo.

power, where as Walsh et al [10] determined the coefficient to be about 2.1. Wen and Chen [5] reported a correlation for particle flux which is proportional to bubble diameter and (Uo/Umf - 1) to the 5/2 power. These correlations are listed in table 6.

# TABLE 6

Wen and Chen B = 1.34 (04) (Uo-Umf) kg/m sec

Walsh et al B = 18 (Uo - Umf) kg/m sec

Comparison of least square fit relations for Po as functions of Uo and Umf.

The differences in these correlations are due to the different bed configurations in which the data was taken and the measurement technique used. The present work utilized a bed with a relatively closely spaced tube configuration and steel grit (S.G. 8.1, median size 230 microns) for the bed mass. Both ascending and descending particle fluxes were captured in the sample. The work of Walsh et al [10], used a bed with two (2) widely spaced horizontal serpentine tubes and Ottawa sand (S.G. 2.6, median size 755 microns). Also, only descending particle flux was used in determining their relations. The correlations of Wen and Chen [5] are a result of studies conducted on previous research using cylindrical column beds and low mass bed materials

(S.G. 0.8 - 2.6). The data for these analysis is based mainly on pressure measurements.

It has been observed by Lewis et al [3] and Wen and Chen [5] that a is not a strong function of Uo. Both of these studies recommend that the characteristic particle decay length, 1/a, could be approximated by an expression of the form:

the confidence with the control of the second of the control of th

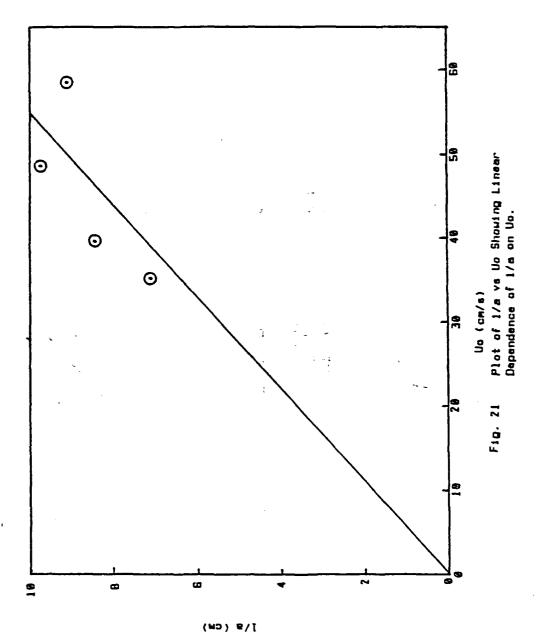

$$1/a = C Uo \tag{11}$$

Table 7 is a list of correlations obtained by other studies and in the present work. The study by Lewis et al [3] was conducted with 75 micron glass spheres in a cylindrical bed. Fig. 21 shows the relationship between 1/a and Uo in the present work.

Comparison of least square fit relations for 1/a as functions of Uo (m/s).

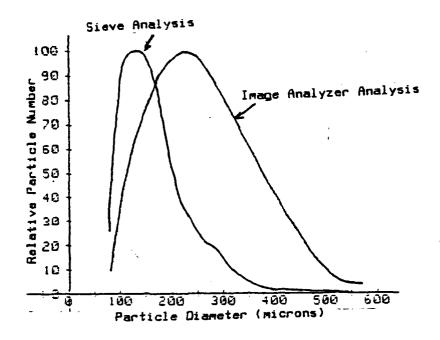

# Particle Size Distribution

Two methods for determining particle size distribution were used. The sieve method, described in Appendix E, was used for bed material analysis only, due to the small sample sizes obtained from the trap. To analyze the small trap samples, an image analyzer was utilized. The procedure used with the image analyzer is described in the experimental procedure chapter.

The sieve data representing bed mass as a function of particle size, is listed in Appendix E. Fig. 22a shows the bed mass data converted to particle number as a function of particle diameter where the interval of particle diameter between successive measurements is 10 microns. These plots are faired from the data listed in Appendicies E and J. Fig. 22b shows the bed mass distribution. The conversion from a mass distribution to a particle number distribution was calculated assuming that each particle was spherical in shape. The volume corresponding to a given particle diameter was multiplied by the particle density to get a unit particle mass. The mass fraction of the sieve analysis corresponding to the specified particle diameter was then divided by the unit particle mass to obtain the representitive particle number. The overall resulting particle number distribution curve was then normalized with respect to a maximum value of 100.

The particle size distribution data obtained from the image

a) Particle Distributions

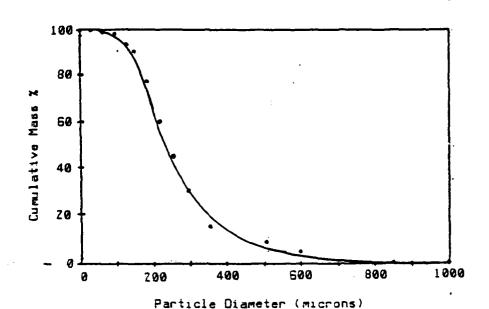

Fig. 22 Particle Size vs Mass distribution and Particle Number of Bed Material.

b) Mass Distribution

analyzer is listed in Appendix J. The image analyzer was used to analyze the bed mass and sample data from the Uo/Umf = 3.81 data set. The bar graphs and the cumulative percentage plots show the number of particles viewed by the image analyzer plotted as a function of normalized particle diameter.

Fig. 22a shows a plot of the particle number distribution as a function of particle diameter as determined by the image analyzer. The data is normalized with respect to 100 and is compared with the data as determined by the sieve analysis. The descrepancy between the two plots can be explained by the methods used to determine the respective data. The analyzer first determines the cross sectional area of the viewed particle. A circle, having the same cross sectional area, is then calculated. This results in averaging the smaller minimum diameter with the larger maximum diameter of all particles with long cylindrical or ellipsoidal shapes. In the sieve however, a large portion of the particles will pass through the sieve screen by means of the small cross sectional area presented by their longitudinal direction. To be consistant in the following sections, the image analyzer data will be used to correlate all particle density distributions.

The particle size distribution as a function of height above the bed surface was evaluated using the data collected at Uo/Umf = 3.81. The image analyser was used to determine the distribution by viewing three (3) random samples from each of the six (6) height positions. Table 8 lists the various statistical values

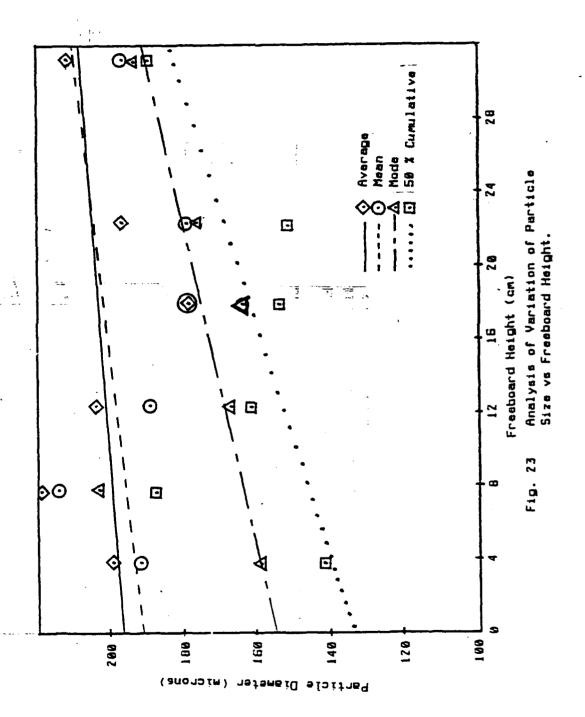

for the particle size distribution data obtained (Appendix J).

TABLE 8

Freeboard Height	Average Diameter	Median Diameter	Mode Diameter	Diameter at 50% of Cumulative Number Distribution
(cm)	(microns)	(microns)	(microns)	(microns)
3.8	199	192	142	159
7.6	219	214	187	203
12.3	204	189	162	167
17.8	179	164	154	179
22.2	197	179	152	177
31.1	<b>Z1Z</b>	197	194	190

Staistical values for particle number distribution as a function of freeboard height. A complete listing of the data is given in Appendix J.

Fig. 23 shows these values plotted against the bed height at which they were taken. The excursion of points at the 7.6 cm height is assumed to be due to analysis error. The linear regression lines for the average and median values show that they are weak functions of collection height. For the particle diameter values representing the mode and the 50% point on the cumulative percentage plot, the linear regression lines show a stronger dependence on collection height.

# Oscilloscope Trace Analysis

Figs. 24 thru 27 show examples of the oscilloscope traces given in Appendix K. Figs. 24 and 25 represent the traces obtained during low Vo coditions. Under these conditions, the normal bubble probe output is high (+ 5 volts dc). When a bubble errupts, particles are thrown from the surface of the bed and eclipse the light path at the tip of the probe (trace goes to zero). Figs. 26 and 27 represent the traces obtained at higher Vo conditions when the bubble probe is normally eclipsed (bubble probe output is low, zero) by particles. The presence of a bubble is detected by a high\_output\_from the bubble probe due to the bubble creating a void through which the light beam can pass. The anemometer output just above the bubble probe is used to determine the velocity of the gas jet leaving the erupting bubble. As seen in the figures, there is not always a bubble associated with a gas jet and vice versa. This is due to the anemometer probe being slightly offset from the bubble probe as described in the experimental procedure section.

The gas jet in Fig. 24 is delayed 5 ms and the gas jet in Fig. 25 is delayed 35 ms from the point where the bubble traces begin their excursion to the zero (eclipsed) condition. Since the separation between the bubble probe and the anemometer is 1 cm, this results in an estimated jet velocity of 200 cm/s (Fig. 24)

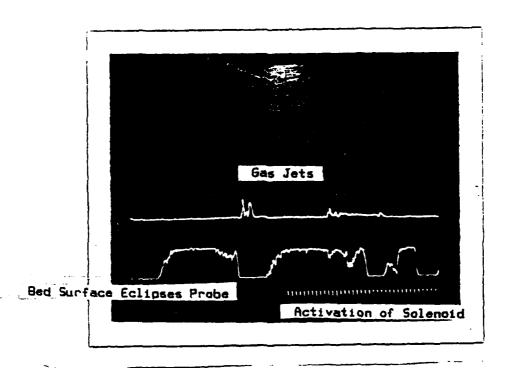

Fig. 24 Oscilloscope Trace of Bubble Probe, Anexometer Probe, and Solenoid Actuation at Lou Vo.

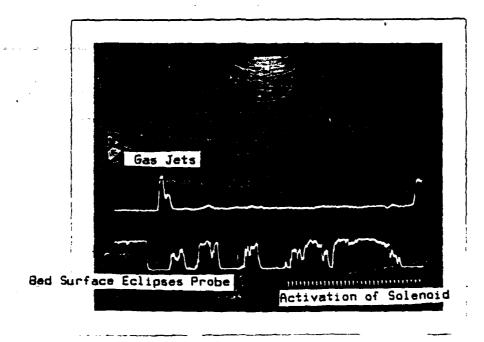

Fig. 25 Oscilloscope Trace of Bubble Probe, Anemometer Probe, and Solenoid Actuation at Low Uo.

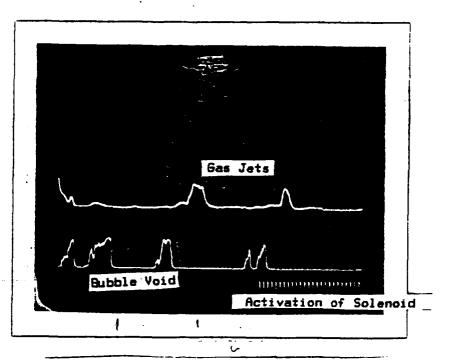

Fig. 26 Oscilloscope Trace of Bubble Probe, Anemometer Probe, and Solenoid Actuation at Higher Uo.

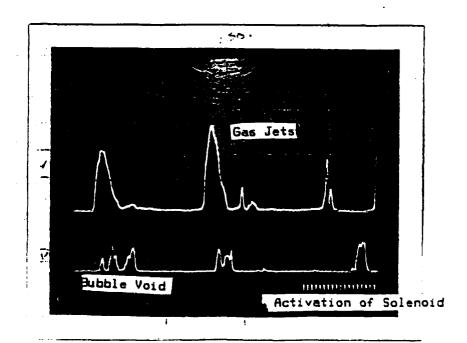

Fig. 27 Oscilloscope Trace of Bubble Probe, Anemometer Probe, and Solenoid Actuation at Higher Uo.

and 28 cm/s (Fig. 25). Using the calibration curve in Appendix M, the velocities are determined to be 518 cm/s for the jet in Fig. 24 and 792 cm/s for the jet in Fig. 25. The large difference in these values could be due to a bulge in the bed surface from the bubble underneath eclipsing the bubble probe. If this is the case, there would be a delay between the time at which the bubble probe was eclipsed and the eruption of the bubble from the bed surface.

An analysis of Figs. 26 and 27 results in the same discrepancies between velocities calculated from delay times and measured by the anemometer probe. Fig. 27 shows another phenomena which occurs quite frequently. The gas jet appears before the which occurs quite frequently. The gas jet appears before the explain these occurances. First, the bubble occurs off center from the bubble probe. Under this condition, the bubble may erupt and initiate a jet which is registered by the anemometer. The bubble then continues to rise and the side of the bubble is registered by the bubble probe. This explanation can be altered to include bubbles coalescing below the surface. Under this condition, a bubble may be pulled into the vortex of an already erupting bubble and it eclipses the bubble probe.

An analysis of the jet velocities and durations for all the oscilloscope traces in Appendix K, resulted in the data listed in table 9. In later calculations, the values to be used for the jet velocity and duration will be 609.6 cm/s (20 ft/s) and 20 ms

respectively.

# TABLE 9

	Averag	je	Stnd Dev	
Jet Velocity	689 22.5	cm/s ft/s	533 18.	cm/s ft/s
Jet duration	21.25	MS	13.22	MS

Average and standard deviation of jet velocity determined from oscilloscope traces in Appendix K.

# Sample Weight Versus Bed Activity Correlation

The main purpose of inserting the bubble and anemometer probe beneath the sampling apparatus was to determine whether a correlation exists between the sample weight collected and the presence of bubble eruptions and gas jets. To evaluate the photographs taken of the oscilloscope traces (Appendix K), the following information was required:

- A. The average velocity of the particles as they travel from the bed surface to the trap.
- B. The distance the particle must travel to reach the trap.
- C. The closure time of the trap relative to the bubble eruptions and gas jets.

The average particle velocity was calculated by determining the average particle size and using the height output from the computer trajectory model. The average particle size as determined by the image analyzer was 180 micons. To determine the average velocity using the model, the following initial conditions were input to the program:

Superficial velocity (Uo) = 57.9 cm/s (1.9 ft/s)

This was the actual velocity measured during sampling.

Jet velocity (Uj) = 609.6 cm/s (20 ft/s)

This value was determined from the anemometer data.

Jet duration (t jet) = 20 ms

This value was determined from the oscilloscope traces.

The height attained by a 180 micron particle, as determined by the model with the above conditions is 44.7 cm in 0.295 seconds. This results in an average velocity of 44.7/0.295 = 151.5 cm/s (4.97 ft/s).

The distance a particle must travel to reach the center of the trap from the bed surface is obtained from the data listed in Appendix I. Since trap height is measured from the bed surface to the bottom of the trap, 4 cm (0.13 ft) must be added to the trap

heights to obtain the distance to the center of the trap. The total time required for the particles to leave the bed surface and arrive at the center of the trap can now be determined. Table 10 shows the transit time for each set of data for which the oscilloscope traces were photographed (Appendix K).

TABLE 10

Data	Trap	Trap	Total Transit	Time Before
set	Height	Height		
Number	Bottom	Center	Time	Actuation
	(cm)	(cm)	( MS )	(ms)
56-65	24.13	27.13	179	136
66-75	25.03	30.03	198	155
76-85	22.23	26.23	173	1 30
86-95	24.76	<b>28.76</b>	190	147
96-105	13.65	17.65	116	73

List of transit times for particles traveling from the bed surface to the center of the trap. The time prior to actuation of the sample trap is also shown (Total time - 42.6 ms).

The total closure time of the sampling apparatus (closure of solenoid power supply switch S1 until trap is shut) is determined in Appendix D to be 42.6 ms. This value is subtracted from the particle transit time to obtain the time before actuation in which particles leaving the bed surface will be caught in the trap.

To determine whether or not a correlation exists between the

weight of a sample and the amount of bed activity present in the bed, a weighted analysis was used. Each sample was evaluated three ways. First, if the sample weight was less than the average sample weight, a weight factor (W) of -1 was assigned to it. If the sample weight was greater than the average, a weight factor of +1 was assigned. Second, the oscilloscope trace was analyzed at the point corresponding to the "time before actuation" listed in Table 10. This position is the time before the solenoid power supply trace is present (Fig. 28). If the trace showed signs of a bubble eruption or a gas jet at this point, the position factor (p) was assigned a value of +1. If no activity was present, the position factor was assigned a value of -1. Third, each trace was analyzed again at the "before actuation time" but bed activity within a +/- 25 ms region was counted. If there was bed activity within this region, the region factor (r) was assigned the value of +1. If no activity was present, the region factor was assigned the value of -1. The following equation was used to assign a correlation factor to each sample:

$$Q = U_D + U_C \tag{10}$$

where:

Q = Correlation factor

p = -1 if no activity is present in bed
 tl if bubble or gas jet activity present

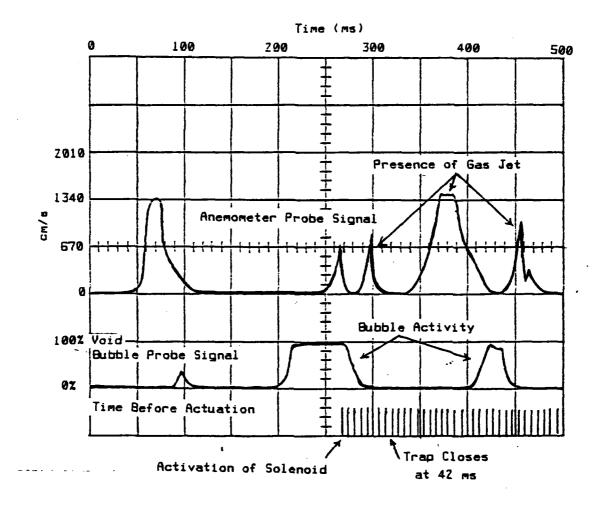

Fig. 28 Typical Oscilloscope Trace During Sampling Procedure.

r = -1 if no activity is present +/- 25 ms +1 if activity is present +/- 25 ms

Table 11 shows the correlation factor for each sample. The resulting average correlation factor for all samples is 0.32. This value suggests that no correlation can be made between the sample weight and bed activity. There are several explanations for this. Bubbles not detected by the bubble probe or debris from previous bubbles returning to the bed surface can influence the sample weight by increasing the amount of particles collected. Also, bubbles of smaller size have a smaller velocity and would therefore produce a particle stream which is either slower or just delayed in leaving the bed surface. This would result in lower sample weights than expected.

#### CHAPTER VI

### TRAJECTORY MODEL RESULTS AND DISCUSSION

### Selection of Baseline Parameters

The input to the model consists of the following five (5) parameters:

- 1) Superficial bed velocity (Uo)
- 2) Initial particle velocity (Upo)
- 3) Peak gas jet velocity (Uj)
- 4) 6as jet duration (tj)
- -- 5) Particle distribution of the bed mass

The baseline values for each of these inputs was determined to be as close to the actual experimental bed conditions as possible.

# Superficial Bed Velocity

The superficial bed velocity was determined directly from the experimental data. For the bed conditions discussed in this section, the superficial velocity used is the same as the highest velocity condition under which the particle sampler was used. The superficial velocity within the bed for these samples was

calculated to be 57.9 cm/s (1.9 ft/s).

Initial Particle Velocity

To determine the initial velocity of the particle, it was assumed that the particle was located at the nose of a bubble and would therefore have the bubbles velocity. To determine the bubble velocity, Kunii and Levenspiel [1] give the following equation:

where:

...... 27 \_\_\_\_\_

Ub = Bubble velocity Uo = Superficial bed velocity Later Transport Unf = Minimum fluidization velocity Ob = Bubble diameter graviatational acceleration

Observations of the bed material during the sampling operation suggests that the average bubble diameter present in the bed is approximately 6 cm (2.4 in). For Uo = 57.9 cm/s, Umf = 15.2 cm/s and Ob = 6cm, the bubble velocity is calculated to be 97.2 cm/s (3.19 ft/s). This value was used as the initial particle velocity for the base line data.

### Peak Gas Jet Velocity

To determine an average peak jet velocity, the anemometer output on the oscilloscope traces (Appendix K) were analyzed. To determine the relationship between the voltage output from the anemometer (which is displayed on the oscilloscope) and the actual gas jet velocity, the anemometer was calibrated in a wind tunnel. The resulting calibration curve for the anemometer output, as displayed on the oscilloscope trace, is given in Appendix M. The average peak velocity of the anemometer traces analyzed in chapter V was determined to be approximately 609.6 cm/s (20 ft/s).

#### Gas Jet Duration

baseline, the anemometer traces in Appendix K were used. The time duration of each gas jet analyzed is determined directly from the oscilloscope trace. The average duration of a gas jet was determined to be approximately 20 ms in chapter V.

#### Particle Distribution of the Bed Mass

Two particle distributions for the bed mass were available for use as the baseline data. Both particle distributions were determined using the same sample but analyzed using different analysis techniques. The two methods used are the sieve method and the image analyzer method, both of which are described earlier

in chapter V. The two distributions are shown in Fig. 29.

The bed distribution determined by the image analyzer was used to be consistent with the particle distributions measured at various freeboard heights.

## Typical Output Using Baseline Parameters

Fig. 30 shows the resulting maximum particle height obtained as a function of particle diameter for the baseline conditions. The general shape of the curve is determined by the dominating force acting on the particle. For large particles, the dominating force at these air velocities is gravity. Therefore, momentum (initial particle velocity) is the controlling factor determining the maximum height attained by the particle. As the particle size decreases, the proportion of drag force to gravitational force becomes larger. For the smaller particles, the drag force becomes the dominate force. The result is that the maximum height attained by a particle continues to increase as particle size decreases. This continues until the value of Uo approaches the terminal velocity of the smaller particles. At this point, the particle is totally dominated by the air flow in the bed. This is seen in the small decrease in height attained by particles less than 110 microns as a result of the particles rapid deacceleration to Uo after the gas jet has stopped while the larger particles continue a little higher due to momentum. The particle height continues to decrease for a short time until Uo becomes equal to

Faired Data From Appendix E and J. Interval of 10 microns.

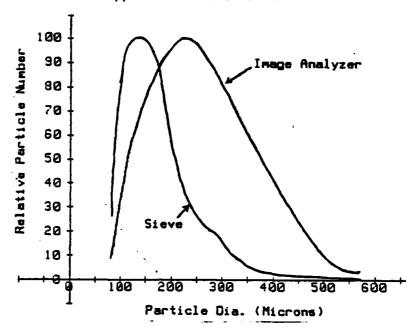

Fig. 29 Relative Particle Number Distributions of Bed Material by Sieve and Image Analyzer Analysis.

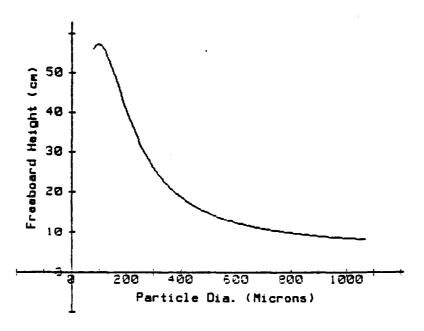

Fig. 30 Maximum Particle Height vs Particle Diameter for Baseline Conditions.

or greater than the terminal velocity for the remaining particles.

These particles would be elutriated from the system.

Figs. 31 thru 36 show the individual particle densities at different heights above the bed. All of the heights show an increase in particle density for the smaller diameter particles. This is the result of the smaller particles falling at their respective terminal velocities which is slower than for the larger particles. The result is that the smaller the particle velocity, the longer the particle exists within a given height region and thus, the larger the particle density. It is also due to the larger number of smaller particles present within the system.

Fig. 37 shows the particle density distribution above the bed. The two curves represent the effect of varying the range of particle diameters used in the model. The two ranges are 80 - 570 microns and 80 - 1070 microns. The peak of the 80 - 570 micron distribution is at about 18 cm of bed height whereas the other distribution peaks at about 11 cm. The region shown on the graph below these heights is the area known as the splash zone. The shape of this part of the curve is due to the initial acceleration of the particles leaving the surface of the bed by the gas jet. The particles then begin to slow down due to drag and gravity resulting in an increase in particle density. The peak on this curve coincides with the maximum height attained by the largest particles, and therefore, it can be assumed that the change in slope is due to the loss of particles as they return to the bed.

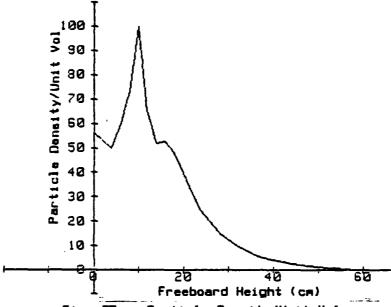

Fig. 37 Particle Density/Unit Volume vs Freeboard height for Baseline Conditions.

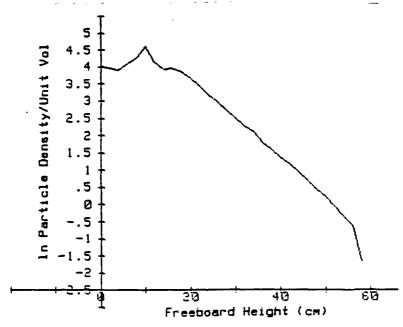

Fig. 38 In Particle Density/Unit Volume vs Freeboard height for Baseline Conditions.

Fig. 38 is a semi-In plot of the same data as plotted in Fig. 37. The sharp drop at the right end of the plot is due to analyzing particles with a minimum diameter of 80 microns. Had smaller particles been included, the slope would have approached zero instead of infinity which would model the elutriation of particles. The slope of the line to the right of the peaks shown in Fig. 38, which are located at 11 and 18 cm of height above the bed surface are the same and are approximately -0.117 grams/cm. To decrease computation time, the 80 - 570 micron particle distribution was used in the following sensitivity analysis as the decay slopes are equal.

## Model Sensitivity Analysis

The parameters changed and the values used are as follows:

Superficial velocity (Uo):

Baseline Uo: 57.9 cm/s (1.9 ft/s)

1. 30.5 cm/s (1 ft/s)

2. 91.4 cm/s (3 ft/s)

Initial particle velocity (Upo):

Baseline Upo: 119.2 cm/s (3.19 ft/s)

1. 61.0 cm/s (2 ft/s)

2. 152.4 cm/s (5 ft/s)

3. 305.0 cm/s (10 ft/s)

Gas Jet velocity (Uj):

Baseline Uj: 609.5 cm/s (20 ft/s)

1. 305.0 cm/s (10 ft/s)

2. 457.2 cm/s (15 ft/s)

Gas jet duration (tj):

Baseline tj: 20 ms

1. 10 ms

2. 30 ms

Particle distribution of bed mass:

\_\_Baseline\_distribution: Image Analyzer

.... . Sieve analysis data

The bed characteristics which are evaluated against the baseline characteristics are:

- The maximum height attained by each particle from 80 to 570 microns.
- 7. The density of each particle size (80 570 microns) at freeboard heights of:
  - a. 4 cm (1.5 in)
  - b. 8 cm (3.1 in)

- c. 17 cm (4.7 in)
- d. 18 cm (7.1 in)
- e. 22 cm (8.7 in)
- f. 31 cm (12.2 in)
- 3. The particle density distribution in the freeboard.

Variation of Superficial Velocity (Uo)

Fig. 39 shows the influence of Uo on the maximum height attained by the particles. As was described in the previous section, the larger particles are dominated by momentum and not drag. This is shown in Fig. 39 by the small change in maximum theight attained by the large particles due to a change in Uo. As the particle size decreases, the drag force becomes the dominate force and the effect of Uo on particle height increases. As seen in Fig. 39, a change in Uo produces a moderate change in the maximum height attained by the small particles.

Figs. 40 thru 45 show the effect of Uo on individual particle densities at different heights above the bed. All of the heights show an increase in particle density for the smaller diameter particles as Uo is increased. This is the result of the smaller particles falling at their respective relative terminal velocities which is slower for smaller particles. A decrease in the maximum particle diameter present at a given freeboard height as Uo is decreased can be observed in Figs. 40 thru 45. This

decrease is due to the decrease in lift given to the ascending particle as Uo is decreased. As a result, all particles achieve a lower maximum height when Uo is decreased.

Fig. 46 shows the effect of Uo on the particle density distribution above the bed. There is a slight increase in overall particle density with an increase in Uo. As expected, there is also an increase in the maximum height attained by the particles with an increase in Uo. Fig. 47 is a semi-In plot of the same data plotted in Fig. 46. Table 12 lists the slopes of the lines to the right of the peak shown in Fig. 47 which is located at about 18 cm of height above the bed surface. This table shows an increase in the particle distribution slope as Uo is decreased.

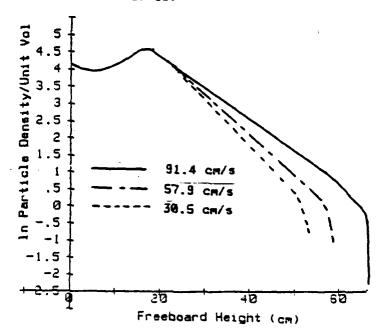

Fig. 47 In Particle Density/Unit Volume vs Freeboard height as a Function of Uo.

Variation of Initial Particle Velocity (Upo)

Fig. 48 shows the relation between initial particle velocity (Upo) and the maximum height attained by particles of different size. This figure also shows that the larger particles are mainly momentum dependent while the smaller particles are drag dependent. If Upo were increased further, the larger particles would continue to increase their maximum height. The smaller particles would approach a height limit which is dependent upon the superficial velocity in the bed.

Figs. 49 thru 54 show the effects of increasing Upo on the individual particle densities for increasing heights. In general, the individual particle distributions undergo the same relative changes from the bed surface to the maximum height position. The difference being the height above the bed surface at which the particular distribution is present.

Fig. 55 shows the effect of varying Upo on the particle density distribution in the freeboard. As was noted previously, the peak density occurs at the point where the largest particles attain their maximum height above the bed. As Upo is increased, the curve to the right of the peak becomes shorter and steeper. This trend will continue until the the effect of the smaller particles returning to the bed cause the slope to decrease. Fig.

Variation of Jet Velocity (Uj)

Fig. 57 shows the effect on maximum particle height when Uj is varied. As in the two previous analysis', the influence of momentum and drag on the different particle sizes is apparent. A decrease in jet velocity from the baseline value results in a large drop in small particle height and a small change in large particle height. This suggests that jet velocity has a strong effect on the dispersion, or seperation of particles of different sizes at increasing freeboard heights. Increasing Uj results in a stretching effect of the particle size distributions above the

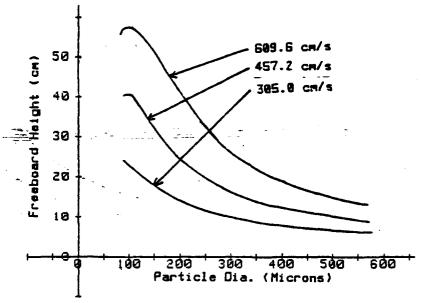

Fig. 57 Maximum Particle Height vs Particle Diameter as a Function of Uj.

bed. One interesting point to note is the loss of the rounded edge at the heights corresponding to the smaller particles. This shows the extremely large effect that drag plays when the air velocity is very close to the terminal velocity of the particle.

Figs. 58 thru 63 show the effect of varying Uj on the individual partical densities at varying heights above the bed. Again, as in the previous parameter analysis, the same distribution shapes can be seen for each value of Uj, the only difference being the height at which it occurs.

Fig. 64 shows the change in particle density distribution as Uj is varied. Fig. 65 is a semi-ln plot of this data showing that as Uj is decreased, the slope of the distribution changes substantially. Table 14 also shows this effect.

Variation of Jet Duration (tj)

duration on the maximum heights attained by the particles. It is easily seen that a small change in jet duration results in a substantial change in particle height. This effect indicates that the distribution present in an actual fluidized bed is probably a statistical average of a rapidly-fluctuating particle distribution which is controlled by the durations of the jets from the neighboring bubble eruptions as well as local eruptions.

density distributions, at different freeboard heights, as a function of jet duration. These figures also show the drastic change in density distributions caused by changes in jet duration.

Fig. 73 shows the particle density distributions above the bed as affected by jet duration. Fig. 74, which is a semi-ln plot of the data, shows the drastic changes in the decay slopes. Table 15 also shows this drastic variation in slope.

this analysis. The determination of these distributions used in described earlier in this work.

particle distribution on the individual particle distributions at different heights above the bed surface. Using the sieve particle distribution instead of the image analysis distribution produces a shift in the mean particle distribution towards the smaller particles. The distributions resulting from the sieve data do not shift as much as the image analyzer data when the freeboard height is increased. The small shift in mean diameter exhibited by these plots is consistant with the distributions listed in Appendix J.

Fig. 82 shows the particle density distributions in the

freeboard for the two bed mass conditions. The effect of the sieve distribution (which has a much lower average particle diameter) is to decrease the initial rate at which particle mass returns to the bed. This is due to the smaller particles having a much smaller terminal velocity. This will not only raise the bulk of the particles to a higher height, but will also increase the time required for the particles to return to the bed.

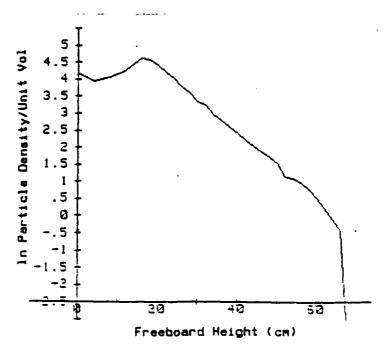

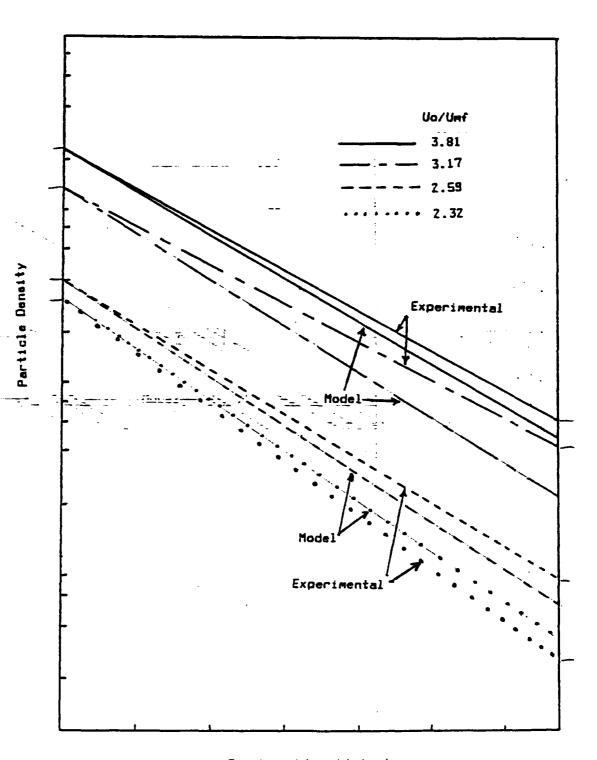

Fig. 84 In Particle Density/Unit Volume vs Freeboard height for Baseline Conditions.

distribution line after the peak value in Fig. 84 with the slope obtained from the experimental data shows very good agreement between the two. This data is also given in Table 17 along with the data obtained for the other experimental data sets and is shown plotted in Fig. 85. The slopes for the model data show a steady increase in slope as Uo/Umf is decreased. This trend is also followed by the experimental data but is not as smooth. The slope of the experimental data is also changing faster than the slope of the model data. One reason for this is that all the model calculations were performed using the same value for jet velocity and duration of 609.6 cm/s and 20 ms respectively. The magnitudes values to be used for these different conditions could not be determined.

Comparison of slopes for the particle density distributions above the bed as derived from the experimental data and the computer model.

# Freeboard height (cm)

Fig. 85 Comparison of slopes for the particle density distribution above the bed as derived for experimental data and computer model output.

The slope shown in Fig. 84 for heights between approximately
4 and 18 cm is totally different from the slopes listed in table
17. This is also the lower range in which the experimental data
was collected. As was shown earlier, when the particle
distribution analyzed included particles from 80 - 1070 microns,
the peak was located at 11 cm. This is the height where the
largest particles attain their maximum height and begin to fall
back to the bed. It does not seem likely that including the few
particles present above 1070 microns would totally account for
this discrepancy. Other factors which the model has not accounted
for which may explain these discrepancies is the effect of varying
discrepancy in the second of particles whose velocity vector is not
discrepancies in the bed surface.

# CHAPTER VII

# CONCLUSIONS AND RECOMMENDATIONS

## Conclusions

Several important conclusions can be made concerning the particle trajectory computer model and the experimental data.

discussed in this work, produces results which closely predict

several aspects of particle activity within a fluidized bed. The

more important predictions include the particle density

distribution in the freeboard and the height distribution of

particles. The results obtained with the current model indicate

that further work on improving the particle trajectory model to

include particle-particle interactions and paticle velocities not

perpendicular to the bed surface is very desirable.

2. The sensitivity analysis indicates that the jet duration and jet velocity are critical parameters in determining particle loading conditions in the freeboard. Since these are constantly changing from one bubble eruption to the next, a statistical distribution will be required to accuarately model freeboard particle activity. The development of a basic model to predict

the jet duration and velocity as a function of bubble size, Uo, Umf, etc is therefore needed.

- 3. Particle distribution analysis of experimental samples at increasing heights above the bed, show the presence of large particles. Many of these are above the maximum calculated trajectory heights for these particle sizes. This indicates that either the jet velocity or jet duration carried these particles to these heights, or, particle-particle collisions are present in numbers great enough to be important in the analysis.
- appears to operate satisfactory. The data obtained correlates with work done by other researchers and with the computer model. However, additional work is needed to correlate sample size and particle size distribution with freeboard height.

## Recommendations

1. Further experimental data is needed at higher velocities and higher heights above the bed using the sampling apparatus designed in this work. This will provide additional data to evaluate the operation of the sampling apparatus and the computer model. Also, a scale capable of measuring quantities of samples less than 0.01 grams and a particle removal system which removes the particles with less error from the sample trap is necessary for accurate work.

- 2. A sampling device which has a shorter trap height should be designed. The present sample trap is very direction oriented and samples particles traveling only in a narrow range from the vertical. This would allow more accurate work to be done in the splash zone where particles are more likely to be traveling in directions other than vertical.
- 3. The computer model needs to have encorporated in it, a statistical distribution model for jet velocity and jet duration.

  This will allow the determination of the effects of varying jet velocity and duration on particle distributions in the freeboard.
  - 4. A correlation for jet velocity and duration as functions of bubble diameter, Uo, and Umf should be determined and included in the model.

#### APPENDIX A

# Moment of Inertia Calculations for Paddles

The calculation of the total Moment of inertia (I) of the paddles can be broken up into three seperate calculations. First, the moment of inertia (II) of the two aluminum cylinders used to mount the paddle arms to the solenoid shaft is calculated. The second calculation (I2), accounts for the moment of inertia of the paddles themselves, which are constructed of a foam, basswood and imminus (Fig. 2008) Part of the moment of inertia (I3) of the hardwood mounting ends on the paddles is calculated.

The following equations were used to calculate the mass moments of inertia:

$$I1 = \frac{P + r^4}{2} \tag{A1}$$

$$IZ = L U (L^{2} + U^{2}) (P1 + 1 + P2 + 2)$$

$$IZ \qquad (A2)$$

$$13 = 2 L U + P (L^2 + U^2)$$
12 (A3)

Table A.1 is a listing of parameters required for the moment calculations.

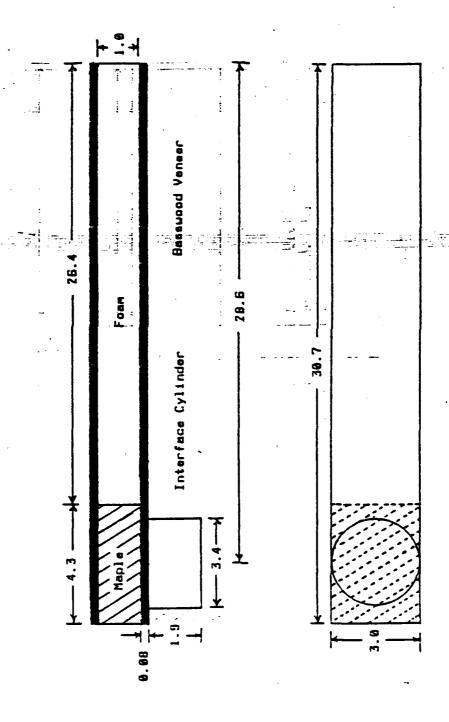

Fig. A-1 Construction of Paddles with Aluminum Interface Cylinder Shown. All Dimensions in cm.

Listing of paddle components and parameters.

Equation (A.1) is used to calculate the mass moment of inertia for a right circular cylinder rotating about its Z axis (Fig. A-Z). The height H, accounts for both the upper and the lower solenoid shaft cylinders. Equations (A.2) and (A.3) determine the mass moment of inertia for a rectangular prism rotating about its:X-Y centroidal axis:(Fig. A-3). The length L resulting all contents are identical and lower paddle lengths. The factor of Z in equation (A.3) is because both the upper and lower hardwood sections are identical and can be combined. By inserting the respective values from Table A.1 into equations (A.1), (A.2), and (A.3), the value for each inertia component can be calculated. Adding these components, the total mass moment of inertia applied to the solenoid by the paddles is determined. These results are listed in Table A.2.

## APPENDIX B

# Error Determination of Vacuum Collection System

Tests of the vacuum sample removal system indicated that some particles remained in the sample trap. These particles were located in the corners of the trap where the equalizing air stream could not agitate them enough to move them into the vacuum stream.

As a result, it became necessary to determine to what extent these recessary to determine the recessary the recessary to determine the recessary the recessary to determine the recessary the recessary to determine the recessary to determine the recessary to determine the recessary the

The procedure used involved placing samples of known weight and particle size distribution (equivalent to the bed material) inside the sample trap. Sample sizes of 10, 15, 20, and 25 grams were used. The sample particles were then vacuumed out and their weight determined. The difference in weights of the samples were then calculated along with the percentage differences. These results are listed in Table 8.1.

An analysis of the results listed in Table B.1 indicates that the average difference between the two sample weights is only 0.52 % while the maximum difference observed was 0.93 %. It can therefore be concluded that the particles remaining in the sample trap do not significantly affect the accuracy of the sample attained.

#### Sample Trap Closure Time Test

size of the sample trap, it was important to ensure that the sample trap was closed in a very short period of time. To measure the closure time, the set-up shown in Fig. C-1 was used.

photo transistor, was used. The diode was powered by a 6 volt battery and the photo transistor was wired directly to an oscilloscope. The electric eye circuit was then placed at a distance of 0.267 m (10.5 in) from the pivot point of the paddles. At this position, the closing time calculation involves only a simple proportion relationship between the paddle and the sample trap widths. The eye was also positioned as close to the trailing edge of the fully closed paddle as possible to minimize error.

The oscilloscope sweep was set to trigger off of the initial change of state from the photo transistor when the paddle first eclipsed the light beam. The resultant traces were then analysed to determine closure time. Time t=0 was set equal to the initiation of the trace on the oscilloscope. Time t=tl was defined as the point at which the trace begins its excursion back

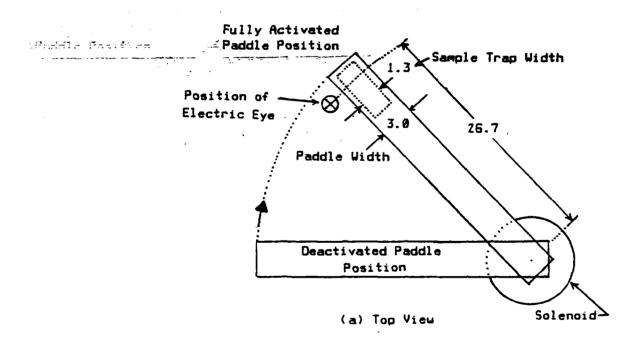

Fig. C-1 Diagram of Closure Time Determination Set Up. All Dimensions in cm.

to the base voltage as shown in Fig. C-2. By using the ratios:

Where:

W1 = width of the paddle

W2 = width of sample trap

W3 = circle time delay measured on oscilloscope

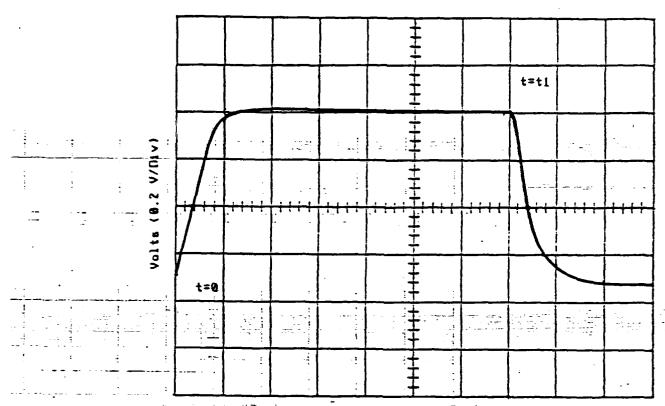

W3 = circle time of sample trap

the closure time of the sample trap can be determined. Several trials were run with the resulting data listed in Table C-1. All trials were very consistant; The resultant determination for the average closure time was 1.44 ms.

#### APPENDIX D

# Solenoid Torque and Dynamic Analysis

I millisecond (ms). At this speed, a particle traveling at 10 meters per second (m/s) would travel i cm or approximately 11 % of the sample trap length. A velocity of 10 m/s is at the upper limit of the particle velocity distribution and would account for only a small percentage of the particles ejected by the bed. The majority of the particles, for the fluidization conditions used in the bed, have an average ejection velocity of 1-2 m/s, based on data from George and Grace [8].

#### TORQUE ANALYSIS

To determine the minimum required torque output of the solenoid, two analysis were performed. The first analysis calculates an average torque required to produce the desired velocity. The second analysis uses the torque data from the selected solenoid and calculates the expected closure time and swing time for the paddle arms.

# First Analysis

To close the sample trap in 1 ms, the angular velocity of the paddles at closure can be calculated as:

$$u = UZ$$
R t2 (D.1)

erromania erregija, mal

The radial acceleration required to attain this velocity through a deflection of \$\frac{10}{17}4\$ radians (45 Deg), is calculated by:

$$a = \frac{\omega^2}{2.8} \tag{D.2}$$

Using the result of equation D1 and  $\theta=17/4$  radians, equation D2 gives the required angular acceleration of the paddles as 1448.5

rad/s/s. Combining this result with the result for the total mass moment of inertia from Appendix A, the required average torque output of the solenoid can be calculated as:

[ = [ a

(D3)

ত স বিষয়েটিলগ হামাhereসংগ্ৰাক স Angular acceleration of paddles

I = Mass moment of inertia

T = Required solenoid torque

The resultant value for the torque (T) is 0.87 N m (7.7 Lbf in).

A geometric average of the selected solenoid's torque output, as shown in Fig. D-1a, Indicates an average of 1.0 N m (8.8 Lbf in).

Therefore, the selected solenoid has sufficient torque output to achieve the desired paddle velocity.

## SECOND ANALYSIS

For the second analysis, it will be assumed that the torque output of the selected solenoid can be modeled as a linear spring. Fig. D-1b shows the torque output of the solenoid as a function of angular displacement. From Fig. D-1b, a spring constant of  $k=0.72\ N$  m/rad  $(0.11\ Lbf\ in/deg)$  can be used to approximate the torque curve. The spring constant is derived from the slope of the torque-angular displacement curve.

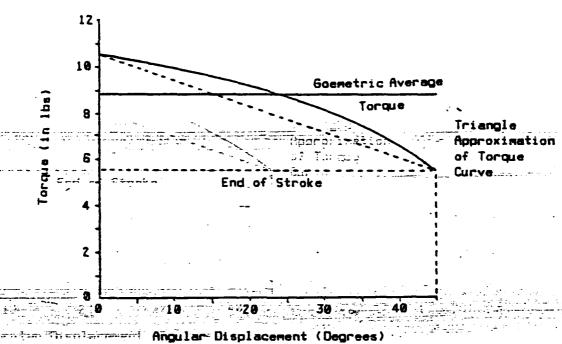

Fig. D-la Torque Output of Rotary Solenoid
Showing Triangle Approximation.

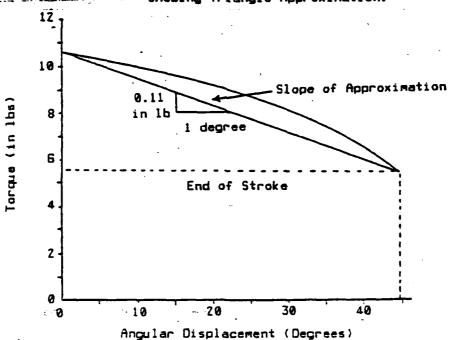

Fig. D-1b Torque Output of Rotary Solenoid Showing Slope of Approximation Curve Used to Determine Spring Constant.

The system can then be modeled as a simple rotational mass - spring system. The differential equation of motion, general solution, and boundary conditions are:

Diff Eqn: 
$$I \theta + k \theta = 0$$
 (D.4a)

= Gen Soln=  $\frac{2}{1} = \frac{1}{1} = \frac{1}{1}$ 

b.c.: 1) t = 0:  $\theta = 0$ 

2) t = 0:  $\theta = 1.65$  rad

Solving equation (D.4b) using the given boundary equations, gives the following expressions for any angular displacement ( $\theta$ ) and angular velocity ( $\dot{\theta}$ ):

$$\theta = 1.65 \cos(\pi t)$$
 (D.5a)

$$\theta = -1.65 \text{ m sin(m t)}$$
 (D.5b)

Knowing that the solenoid stroke is  $\pi/4$  radians, the total solenoid actuation time can be obtained from equation (D.5a) by setting  $0 = (1.65 - \pi/4)$ . The total actuation time was determined to be 29.2 ms. Inserting this value for time into equation (D.5b), a rotational velocity of 48.5 rad/s was found. This velocity is very close to the desired velocity obtained from equation (D.1).

# DYNAMIC ANALYSIS

The desire to determine whether the debris of a specific bubble has been trapped by the sampling device requires the determination of the total actuation time for the apparatus.

Knowing this value, the delay between the detection of a bubble and the closure of the sample trap cambe determined, and hence, whether the particles from the detected bubble were within the vicinity of the trap.

Appendix C determined that the actual closure time for the sample trap was 1.44 ms 2. Using this value in equation (D.1), a cotational velocity at the end of the stroke of only 33.12 rad/sec is calculated. Because the mass moment of inertia for the solenoid was unknown in the beginning, the analysis ignored it.

With the determination of the actual closure time in Appendix C, the total moment of inertia, including the solenoid can be approximated. By iterating equations (D.5a) and (D.5b) with  $\theta$  = 33.12 radians/sec, a new inertia value of 1.27 (-03) kg m is determined. Using this inertia value in equation (D.5b), the total actuation time is 42.6 ms. This increase in actuation time of 13.5 ms is relativily close to the manufactures quoted actuation time for the solenoid of 12 ms and suggests that the values are within reason.

Table D.1 provides a summary of the results obtained from the dynamic analysis.

# APPENDIX E

# Bed Particle Size Distribution Analysis

A sample of particles was obtained from the fluidized bed after the bed had been operating for several hours. Sample sizes, ranging from 1.2 to 2.8 kg, were then taken from the central area of the bed. Each sample was then sieved through a series of 14 US standard wire mesh sieves using a Tyler Industrial Products Model RX-24 portable sieve shaker for 30 minuites. The contents of each sieve was then weighed, using a Torsion Balance Co TORBAL scale, to an accuracy of 0.01 gram. The resulting average particle size distribution is listed in Table E.1 and shown in fig. E-1.

Average particle size distribution of bed material in grams and percentage of total weight using sieve analysis.

# APPENDIX F

# Mean Bed Flow Velocity Determination

To determine the mean velocity of air flowing through the bed, the ASME report on fluid meters [17] was used. Based on this paper, equation (F.1) was used for determining the mass flow rate of air through the bed.

$$W = 0.099702 (KYFd^2) (edP)^{\frac{1}{2}}$$
 (F.1)

where:

W = Mass flow rate (lbm/sec)

d = Orfice diameter (inches)

K = Flow coefficient

F = Thermal expansion factor (1 for air)

Y = Expansion factor

dP = Differential pressure (inches water)

e = Density of air (ahead of orfice)

The flow coefficient (K) is a function of Reynold's number, the orfice diameter (d), and the pipe diameter (D). For the pressure tap configuration used in the MIT atmospheric fluidized bed (1-D / 1/2-D) the flow coefficient is calculated using equation (F.2).

$$K = Ko + \frac{1000 \text{ b}}{\sqrt{B \text{ Re}^2}}$$
 (F.2)

where:

Re = Reynolds No.  
B = 
$$d/D$$
 = (orfice dia / pipe dia)  
Ko =  $(0.6014 - 0.01352 D^{-\frac{1}{4}})$   
+  $(0.3750 + 0.07257 D^{-\frac{1}{4}})$   
(  $\frac{0.00025}{D^{2} B^{2} + 0.00025 D} + B^{4} + 1.5 B^{6} )$   
b =  $(0.0002 + 0.0011)$   
+  $(0.0038 + 0.0004)$   
D  
(  $B^{2} + (16.5 + 5 D) B^{16} )$ 

The expansion factor (Y) is determined from equation (F.3) and is a function of the diameter ratio (B), the ratio of specific heats (s), and the ratio of the differential pressure to inlet pressure.

$$Y = 1 - (0.410 + 0.350 B^{4}) \underline{dP}$$
P1 s (F.3)

where:

Mass flow rate is a function of velocity, and therefore, by definition a function of Reynold's number. Equation (F.4) is used to determine mass flow rate as a function of viscosity and Reynold's number.

$$U = u OZ$$

$$C Re (F.4)$$

where :

u = Absolute viscosity (lbm/ft sec)
C = Constant (15.28)

This requires that the solutions of equation (F.1) and equation (F.4) be iterated until the Reynold's numbers converge. The determination of mean air velocity is obtained from the mass flow rate (W) using equation (F.5).

$$V = \frac{U}{e A} \tag{F.5}$$

where:

e = Density of air (lbm/ft<sup>3</sup>)
A = Area of bed (ft<sup>2</sup>)

To perform these calculations, a computer program was used. The program (APPENDIX 6) is written in HP BASIC 2.0 for running on an HP 9816 series 200 micro-computer. Convergence usually required four to seven iterations and should be correct to within 0.5%.

# APPENDIX G

This Appendix lists the BASIC computer program used to calculate mean bed velocity as discussed in Appendix F. It is written in HP BASIC 2.0.

### APPENDIX J

This Appendix contains the output from the image analyzer.

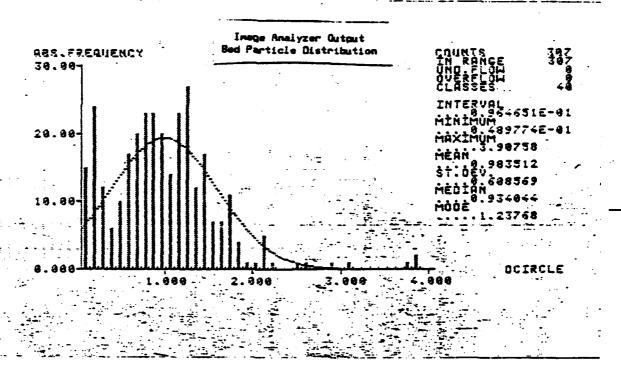

The output is arranged in the following order.

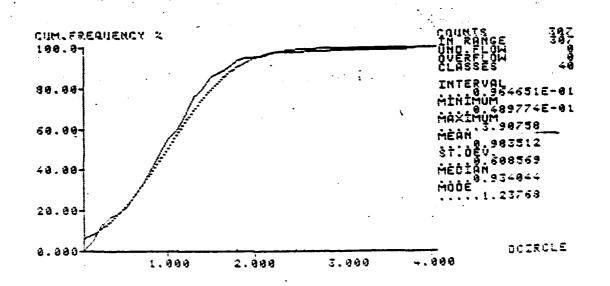

- 1. Bed distribution
- 2. 4 cm freeboard height
- 3. 8 cm freeboard height
- 4. 12 cm freeboard height
- Section 5. Term 18 cm freeboard height
  - 6. 22 cm freeboard height
  - 7. 31 cm freeboard height

Each of the distributions at a given bed height applies only to the Uo/Umf = 3.81 condition. For each of the seven image analyzer outputs listed, the following three formats are used.

- Histogram of absolute particle frequency vs particle diameter.
- Cumulative percentage plot of particle size distribution.
- 3. Table listing of the above data.

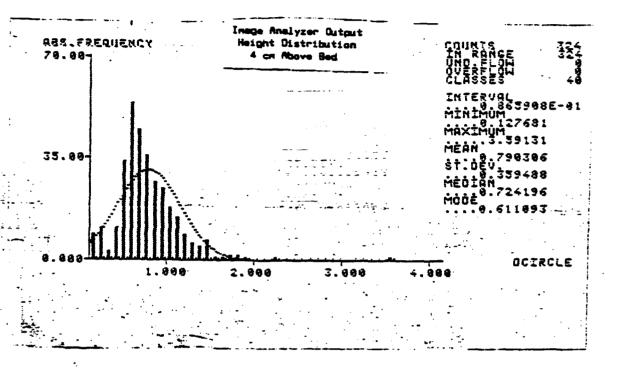

The dashed line on both the bar graphs and on the cumulative percentage plots represent the Gaussian distributions which fit the given set of data. This Gaussian distribution should be used only as a rough estimate of the data because the analysis included "particles" less than 70 microns. By viewing a blank slide with only the tape applied, these "particles" were confirmed to be bubbles and dirt entrapped in the adhesive on the tape used to hold the sample particles in place.

### APPENDIX L

This Appendix contains a complete listing of the particle trajectory computer model used in this research. In addition, an in depth program description and flow diagram is included.

Personal parental received historical

### Model Computer Program

This section describes the computer program listed in Appendix K. To assist in understanding the program logic, the program itself contains numerous comment statements. The program consists of a main program and seven (7) subroutines. The main program controls the input of parameters, trajectory calculations, and output selections. The subroutines control the actual data output in either table form or graphics. The following is an indepth description of the program:

Lines Description

50-150 This section is used to explicitly define the major variables used within the program. The large arrays are defined in common block form to save memory. Constants used in the program are also defined.

198-610 This section is used to input variable data to the program. Three options exist for the bed particle distribution input:

- 1) The default condition sets the quantity of each particle to unity. This option is generally used when a height determination is required or being sought after.
- 2) The particle number option allows the entry of bed distribution by the number of particles present in each diameter range. This is used when data from the image analyzer was being used.
- 3) The last option is used when the particle size distribution is determined from a sieve analysis and the data is measured in grams mass. The program will then determine the

particle number density based on the assumption that the particls are spherical.

659-690	These lines convert the velocity input values from Ft/s to m/s.
700-710	Determine the slope of the triangular jet using the input amplitude and duration.
729-899	Initialize the data arrays to zero (0).
819-1669	This section calculates the trajectory for each diameter particle. This WHILE condition contains the following 8 subsections.
829-840	Initialize the height of the particle to pass the first WHILE statement. Calculate the particle diameter to be used.
850-1340	Calculate the particles trajectory parameters while the particle is above the bed surface. This DO loop contains the following 6 subsections.
1 1 1 1 1 1 1 1 1 1 1 1 1 1 1 1 1 1 1	If the elapsed time since the particle left the bed is less than the jet duration time, the add the jet velocity to Uo.
950-990	Calculates the relative velocity of the air with respect to the particle. Determine the sign of the drag force.
1010-1060	Calculate Reynold's number.
1100-1170	Calculate the drag on the particle and then determine the particles new velocity and position.
1180-1220	If the particles velocity is positive, record the new max height and elapsed time.
1230-1320.	Add I count to the probability array in the storage position representing the particles height/2. By using the DIV statement, a height window (dH) of Z cm is created.
1350-1370	Change all heights from Ft/s to m/s
1380-1430	Multiply probability distribution by bed distribution weighting factor.
1440-1500	Determine the maximum value and normalize

	the data such that the maximum is 100.
1510-1560	Calculate the particle entrainment by summing the total volume of each particle distribution at a given height.
1570~1660	Normalize the entrainment data to 100 and calculate the ln value if not equal to zero.
1700-1820	Display output menu.
1836-2210	Controls the selected output.
2220	End of MAIN program
2260-2520	Sub Display_Data is used to list input parameters used and the maximum height attained by each diameter particle.
2 <b>560~3930</b>	Sub Display_graphics controls the processing and output of graphic information. This subprogram contains the following 4 sections
2640-3120	Performs scaling for determining graphic dimensions and limits.
3130-3240	Creates graphic display and labels the X and Y axis.
3250-3830	Controls the plotting of selected graphic output.
3840-3920	Prints hard copy.
3980-4130	Function routine for determining scaling factor for graphic display.
4180-4280	Finds the limit of data within an INTEGER array to limit the X axis on a plot to the range in which the Y values are non-zero.
4330-4460	Determines the maximum value stored in an

END of PROGRAM

INTEGER array.

4510-4640

4690-4770

Same as 4330-4460 except for REAL array.

Same as 4180-4280 except for REAL array.

### APPENDIX M

This Appendix contains the calibration data for the anemometer probe. The calibration was conducted in a small wind tunnel using a pitot tube connected to a micromanometer capable of measuring pressures to within 0.001 ins. of water.

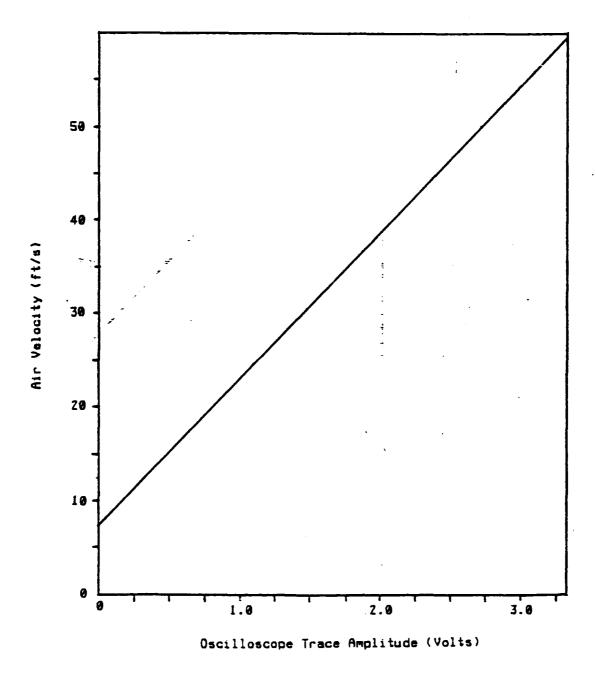

Fig. M-1 Calibration of Anemometer Probe.
Oscilloscope Voltage vs Air Velocity.
